Aortic dissection

Definition

Aortic dissection is a rare, but potentially fatal, condition in which blood passes through the inner lining and between the layers of the aorta. The dissecting aorta usually does not burst but has an abnormal second channel within it.

Description

A defect in the inner lining of the aorta allows an opening or tear to develop. The aorta is the main artery of the body and has high blood pressure. When a defect develops, blood pressure can force the tear to open and allow blood to pass through. Since the blood is under pressure, it eventually splits (dissecting) the middle layer of the blood vessel, creating

KEY TERMS

Dissection—A cut or divide.

Hemorrhage—A large discharge of blood, profuse bleeding.

a new channel for blood. The length of the channel grows over time and can result in the closing off of connection points to other arteries. This can lead to **heart attack**, strokes, abdominal **pain**, and nerve damage. Blood may leak from the dissection and collect in the chest an around the heart.

A second mechanism leading to aortic dissection is medial hemorrhage. A medial hemorrhage occurs in the middle layer of the blood vessel and spills through the inner lining of the aorta wall. This opening then allows blood from the aorta to enter the vessel wall and begin a dissection. Approximately 2,000 cases of aortic dissection occur yearly in the United States.

Causes and symptoms

Aortic dissection is caused by a deterioration of the inner lining of the aorta. There are a number of conditions that predispose a person to develop defects of the inner lining, including high blood pressure, Marfan's disease, **Ehlers-Danlos syndrome**, connective tissue diseases, and defects of heart development that begin during fetal development. A dissection can also occur accidentally following insertion of a catheter, **trauma**, or surgery. The main symptom is sudden, intense pain. The pain can be so intense as to immobilize the patient and cause the person to fall to the ground. The pain is frequently felt in both the chest and in the back, between the shoulder blades. The extent of the pain is proportional to the length of the dissection.

Diagnosis

The pain experienced by the patient is the first symptom of aortic dissection and is unique. The pain is usually described by the patient as "tearing, ripping, or stabbing." This is in contrast to the pain associated with heart attacks. The patient frequently has a reduced or absent pulse in the extremities. A murmur may be heard if the dissection is close to the heart. An enlarged aorta will usually appear in the chest x rays and **ultrasound** exams of most patients. The use of a blood dye in angiograms and/or CT scans (**computed tomography scans**) will aid in diagnosing and visualizing the dissection.

Treatment

Because of the potentially fatal nature of aortic dissection, patients are treated immediately. Drugs are administered to reduce the blood pressure and heart rate. If the dissection is small, drug therapy alone may be used. In other cases, surgery is performed. In surgery, damaged sections of the aorta are removed and a synthetic graft is often used to reconstruct the damaged vessel.

Prognosis

Depending on the nature and extent of the dissection, death can occur within a few hours of the start of a dissection. Approximately 75% of untreated people die within two weeks of the start of a dissection. Of those who are treated, 40% survive more than 10 years. Patients are usually given long-term treatment with drugs to reduce their blood pressure, even if they have had surgery.

Aortic valve insufficiency

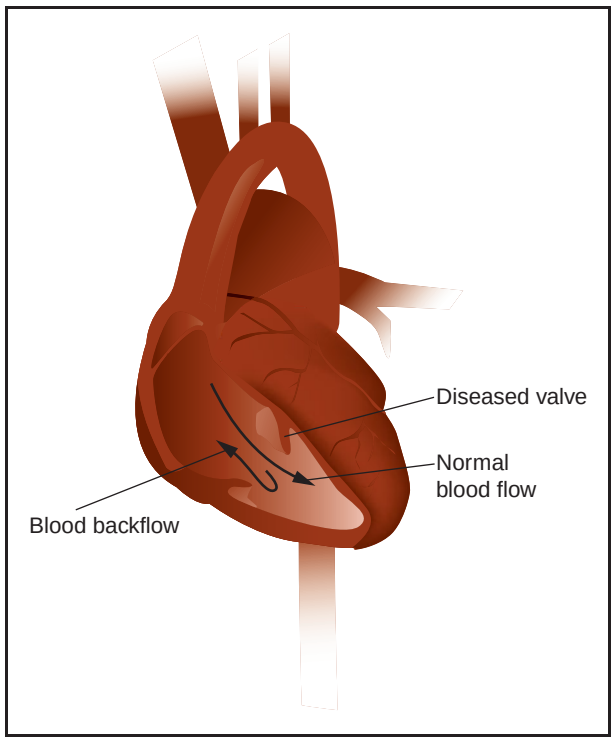
Definition

The aortic valve separates the left ventricle of the heart (the heart's largest pumping chamber) from the aorta, the large artery that carries oxygen-rich blood out of the left ventricle to the rest of the body. In aortic valve insufficiency, the aortic valve becomes leaky, causing blood to flow backwards into the left ventricle.

Description

Aortic valve insufficiency occurs when this valve cannot properly close after blood that is leaving the heart's left ventricle enters the aorta. With each contraction of the heart more and more blood flows

WWW.BOOKBAZ.IR



A human heart with a diseased valve that does not open and close properly, allowing blood to backflow to the heart. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

back into the left ventricle, causing the ventricle to become overfilled. This larger-than-normal amount of blood that collects in the left ventricle puts pressure on the walls of the heart, causing the heart muscle to increase in thickness (hypertrophy). If this thickening continues, the heart can be permanently damaged.

Aortic valve insufficiency is also known as aortic valve regurgitation because of the abnormal reversed flow of blood leaking through the poorly functioning valve.

Causes and symptoms

The faulty working of the aortic valve can be caused by a birth defect; by abnormal widening of the aorta (which can be caused by very high blood pressure and a variety of other less common conditions); by various diseases that cause large amounts of swelling (inflammation) in different areas of the body, like **rheumatic fever**; and, although rarely, by the sexually transmitted disease, **syphilis**.

About 75% of people with aortic valve insufficiency are men. Rheumatic (inflammatory) diseases have been the main cause of this condition in both men and women.

KEY TERMS

Rheumatic fever—A disease believed to be caused by the bacterium group A streptococcus. This bacterium causes a sore "strep throat" and can also result in fever. Infection by this bacterium can also damage the heart and its valves, but how this takes place is not clearly understood.

Aortic valve insufficiency can remain unnoticed for 10 to 15 years. In cases of severe insufficiency a person may notice a variety of symptoms, including an uncomfortable pounding of the heart when lying down, a very rapid or hard heart beat (**palpitations**), **shortness of breath**, chest **pain**, and if untreated for very long times, swelling of the liver, ankles, and belly.

Diagnosis

A poorly functioning or insufficient aortic valve can be identified when a doctor listens to the heart during a **physical examination**. A chest x ray, an electrocardiogram (ECG, an electrical printout of the heart beats), as well as an echocardiogram (a test that uses sound waves to create an image of the heart and its valves), can further evaluate or confirm the condition.

Treatment

Aortic insufficiency is usually corrected by having the defective valve surgically replaced. However, such an operation is done in severe cases. Before the condition worsens, certain drugs can be used to help manage this condition.

Drugs that remove water from the body, drugs that lower blood pressure, and drugs that help the heart beat more effectively can each be used for this condition. Reducing the amount of salt in the diet also helps lower the amount of fluid the body holds and can help the heart to work more efficiently as well.

In cases of a severely malfunctioning valve that has been untreated for a long time, surgery is the treatment of choice, especially if the heart is not functioning normally. Human heart valves can be replaced with man-made valves or with valves taken from pig hearts.

Prognosis

Although drug treatment can help put off the need for surgical valve replacement, it is important to

replace the faulty valve before the heart muscle itself is damaged beyond recovery.

Dominic De Bellis, PhD

Aortic valve replacement

Definition

Aortic valve replacement involves a medical procedure in which an artificial mechanical or healthy tissue value replaces a diseased and failing biological aortic valve. This procedure is performed when any number of diseases causes the aortic value to become leaky (aortic regurgitation) or narrowed (aortic stenosis). For instance, the condition of aortic stenosis can cause the aortic valve to become partially blocked, which prevents some of the blood from flowing through it. An aortic valve replacement is performed by several different procedures, including open-heart surgery, minimally invasive cardiac surgery, and percutaneous (catheter-based) aortic valve replacement.

Purpose

Aortic valve replacement is necessary when the aortic valve has become diseased. The aortic valve can suffer from insufficiency (inability to perform adequately) or stenosis (narrowing). An insufficient valve is leaky and allows blood to flow backward from the aorta to the left ventricle during diastole, which occurs when the ventricles fill with blood. A stenotic valve prevents the forward-moving flow of blood from the left ventricle to the aorta during systole, which is the time period when the heart is contracting.

Either situation can result in **heart failure** and an enlarged left ventricle. With aortic stenosis, the symptoms of **angina** pectoris, **fainting**, and **congestive heart failure** will develop with the severity of the narrowing. There is an increased rate of sudden death of patients with aortic stenosis. Dyspnea (labored breathing), **fatigue**, and **palpitations** are late symptoms of aortic insufficiency. Angina pectoris is associated with the latest stages of aortic insufficiency.

Demographics

Congenital **birth defects** involving a bicuspid aortic valve can develop into stenosis. These patients may become symptomatic in their mid-teen years through the age of 65 years. Patients with a history of **rheumatic fever** have a disposition for aortic stenosis, but may live symptom free for more than four decades. Calcification of the aortic valve tends to affect an older population, with 30% of patients over age 85 having stenosis at **autopsy**. There are approximately 65,000 **heart valve replacement** procedures performed annually in the United States.

Description

The heart contains four chambers: two smaller ones located at the top of the heart called atria and two larger chambers at the bottom called ventricles. Each ventricle has two valves to control the blood flowing into and out of that chamber. The aortic valve controls blood flow out of the left ventricle to the aorta. It opens to allow blood to flow from the heart out to the rest of the body, and it closes to prevent blood from leaking back into the heart. However, the aortic valve may become faulty, and when that happens, surgery may be necessary.

Hospitals with cardiac surgery services provide aortic valve replacement. Specialization is required for young adults and pediatric patients. Cardiovascular and cardiac surgeons are trained to provide this treatment and the initial follow-up care. These surgeons are trained in their cardiac surgical residency to evaluate and perform these procedures and to care for the patient during the postoperative period.

While receiving general **anesthesia** in preparation for the surgery, the patient's cardiac function will be monitored. A sternotomy (incision into the sternum) or thoracotomy (incision into the pleural space of the chest) may be used to expose the heart, with the thoracotomy providing a smaller incision through the ribs. Minimally invasive techniques may also be used, utilizing a partial sternotomy or a lateral minithoracotomy. These approaches seem to decrease patient recovery time, as well as decreasing potential complications. An anticoagulant is administered in preparation for cardiopulmonary bypass. Cardiopulmonary bypass is instituted by exposing and cannulating (putting tubes into) the great blood

WWW.BOOKBAZ.IR

vessels of the heart or by cannulating the femoral artery and vein. A combination of cannulation sites may also be used. The heart is stopped after the aorta is clamped. The base of the aorta root is opened, and the diseased valve is removed. Sutures are placed in the aortic rim and into the replacement valve. The replacement valve will be sized prior to implant to ensure that it fits the patient based on the size of the aortic valve annulus. Once seated, the valve is secured by tying the individual sutures. The heart is then deaired. The cross clamp is removed and the heart is allowed to beat as deairing continues by manipulation of the left ventricle. Cardiopulmonary bypass is terminated, the tubes are removed, and drugs to reverse anticoagulation are administered.

Replacement heart valves can be mechanical or biological tissue valves. For patients younger than 65 years of age, the mechanical valve offers superior longevity. Anticoagulant medication is required for the life of the patient implanted with a mechanical valve. The biological tissue valve does not require anticoagulation but suffers from deterioration, leading to reoperation, particularly in those under the age of 50 years. Women considering bearing children should be treated with biological tissue valves because the anticoagulant of choice with mechanical valves, warfarin, is associated with developmental effects in the fetus. **Aspirin** can be substituted in certain circumstances.

Diagnosis

Initial diagnosis by auscultation (listening) is done with a stethoscope. Additional procedures associated with diagnosis to judge severity of the lesion include **chest x ray**, **echocardiography**, and **angiography** with **cardiac catheterization**. In the absence of angiography, **magnetic resonance imaging** (MRI) or computed tomographic (CT) imaging may be used.

Patients with aortic stenosis who have angina, dyspnea, or fainting are candidates for aortic valve replacement. Asymptomatic patients undergoing coronary artery bypass grafting should be treated with aortic valve replacement, but otherwise are not candidates for preventive aortic valve replacement.

Patients with a history of rheumatic **fever** or syphilitic aortitis (inflammation of the aorta) face the possibility of developing aortic insufficiency. Successful treatment has decreased this causative relationship. Primary causes of aortic valve disease include bacterial **endocarditis**, **trauma**, **aortic dissection**, and congenital diseases.

Patients showing acute symptoms, including **pulmonary edema**, heart rhythm problems, or circulatory collapse, are candidates for aortic valve replacement. Chronic pathologies are recommended for surgery when patients appear symptomatic, demonstrating angina and dyspnea. Asymptomatic patients also must be monitored for heart dysfunction. Left ventricular dimensions greater than 2 inches (50 millimeters) at diastole or 3 in. (70 mm) at systole are indications for replacement when aortic insufficiency is diagnosed.

Preparation

A patient preparing for aortic valve replacement should inform their primary care doctor about any drugs they are taking, including both prescription and over-the-counter drugs as well as herbs or supplements. Make sure that the doctor is aware of a **pregnancy**. For a two-week period before surgery, certain drugs that the patient is taking may be stopped. These usually include those that thin the blood, making it more difficult for blood to clot. Common examples include aspirin, ibuprofen (such as Advil and Motrin), and naproxen (such as Aleve and Naprosyn), as well as **anticoagulant and antiplatelet drugs** like warfarin (Coumadin) and clopidogrel (Plavix). Patients should discuss with their surgeon whether to remain on these and any other drugs they are taking prior to surgery.

If patients smoke, they will need to stop a few days prior to surgery, and patients should inform their surgeon or the surgeon's staff if any new illnesses or medical conditions develop. On the day of the surgery, patients may not to eat or drink anything after midnight the night before surgery is scheduled.

Aftercare

The patient will have continuous cardiac monitoring performed in the intensive care unit (ICU) postoperatively. Medications or mechanical circulatory assistance may be instituted during the surgery or postoperatively to help the heart provide the necessary cardiac output to sustain the pulmonary and systemic circulations. These will be discontinued as cardiac function improves. Once the patient is able to breathe without assistance, ventilatory support will be discontinued. Drainage tubes allow blood to be collected from the chest cavity during healing and are removed as blood flow decreases. Prophylactic **antibiotics** are given. Anticoagulation (warfarin, aspirin, or a combination) therapy is instituted and continued for patients who have received a mechanical valve. The

ICU stay is approximately three days, with final hospital discharge occurring within a week after the procedure.

The patient receives wound care instructions prior to leaving the hospital. The instructions include how to recognize conditions such as infection or valve malfunction, contact information for the surgeon, and guidelines on when to return to the emergency room.

Risks

Risks associated with aortic valve replacement include **embolism**, bleeding, and operative valvular endocarditis. Other risks include breathing problems, **blood clots** in the leg (that may go to the lungs), infection, and adverse reactions to medicines. These risks vary by the age and health of the patient. Hemolysis is associated with certain types of mechanical valves, but is not a contraindication for implantation. Patients are advised not to perform any heavy lifting for four to six months after the procedure is completed in order to avoid damaging the sternum (breast bone).

There are additional risks associated with general anesthesia and cardiopAortic valve replacement accounts for a majority of cardiac surgeries in the United States. Despite technical and medical advances in the various aspects of the procedure, complications remain a leading cause of morbidity and mortality for U.S. patients. Complications from aortic valve replacement include (but are not limited to) damage to bones, organs, or nerves; **heart attack** or **stroke**; and kidney failure.

Alternatives

Balloon valvotomy may provide short-term relief of aortic stenosis, but it is considered a temporary treatment until valve replacement can be accomplished. Aortic valve repair by direct commissurotomy may also be successful for some cases of aortic stenosis. Medical treatment for inoperable patients with severe aortic stenosis is used to relive pulmonary congestion and prevent **atrial fibrillation**.

Severe aortic insufficiency can be treated with medical therapy. Pharmaceuticals to decrease blood pressure, along with **diuretics** and **vasodilators**, are helpful in patients with aortic insufficiency.

Results

Recovery from aortic valve replacement normally takes about three months when the patient is in otherwise good health. Myocardial function typically improves rapidly, with decrease in left ventricle enlargement and size of the inner chamber over several months, allowing the heart to return to normal dimensions. Anticoagulation therapy will be continued, depending on the type of mechanical valve implanted. Implantation of biological tissue valves is associated with the formation of blood clots. If non-cardiac surgery or dental care is needed, the anticoagulant medication will be adjusted to prevent bleeding complications.

Morbidity and mortality rates

There is a 3–5% hospital mortality rate associated with aortic valve replacement. The average survival rate after five years is 85% for patients suffering from aortic stenosis who undergo aortic valve replacement. Structural valve deterioration can occur and is higher in mechanical valves during the first five years; however, biological tissue and mechanical valves have the same failure incidence at 10 years, with a 60% probability of death at 11 years as a result of valve-related complications. Patients with a mechanical valve are more likely to experience bleeding complications. Reoperation is more likely for patients treated with a biological tissue valve, but not significantly different when compared to their mechanical valve counterparts. This combines to an average rate of significant complications of 2–3% per year, with a death rate of approximately 1% per year associated directly with the prosthesis.

KEY TERMS

Antithrombotic—Preventing clot formation.

Biological tissue valve—A replacement heart valve that is harvested from the patient (autograft), a human cadaver (homograft or allograft), or other animal, such as a pig (heterograft).

Diastole—Period between contractions of the heart.

Hemolysis—Separation of hemoglobin from the red blood cells.

Mechanical valve—An artificial device used to replace the patient's heart valve. There are three types: ball valve, disk valve, and bileaflet valve.

Systole—Period while the heart is contracting.

Aortic valve stenosis

Definition

When aortic valve stenosis occurs, the aortic valve, located between the aorta and left ventricle of the heart, is narrower than normal size.

Description

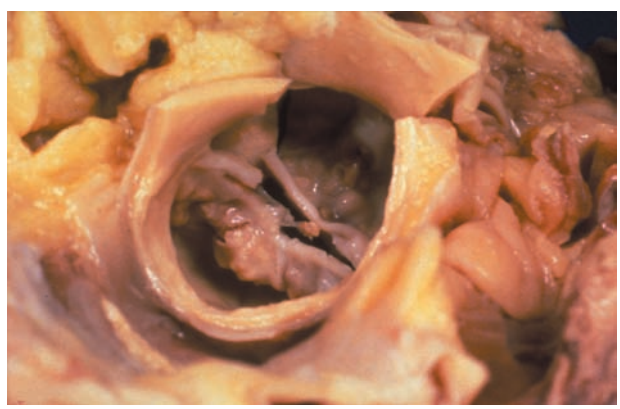
A normal aortic valve, when open, allows the free flow of blood from the left ventricle to the aorta. When the valve narrows, as it does with stenosis, blood flow is impeded. Because it is more difficult for blood to flow through the valve, there is increased strain on the heart. This can cause the left ventricle to enlarge and malfunction, resulting in reduced blood supply to the heart muscle and body, as well as fluid build up in the lungs.

Cause and symptoms

Aortic valve stenosis can occur because of a birth defect in the formation of the valve. **Calcium** deposits may form on the valve with **aging**, causing the valve to become stiff and narrow. Stenosis can also occur as a result of **rheumatic fever**. Mild aortic stenosis may produce no symptoms at all. The most common symptoms, depending on the severity of the disease, are chest **pain**, blackouts, and difficulty breathing.

Diagnosis

Using a stethoscope, a physician may hear a murmur and other abnormal heart sounds. An ECG, also called an electrocardiogram, records the electrical activity of the heart. This technique and chest x ray can show evidence that the left ventricle is enlarged.



A close-up view of a calcified stenosis of the aortic valve. *(Custom Medical Stock Photo, Inc.)*

KEY TERMS

Aorta—The largest artery in the body, which moves blood from the left ventricle to the rest of the body.

Electrocardiogram (ECG)—A test that records the electrical activity of the heart.

Echocardiogram—A procedure in which high frequency sound waves harmlessly bounce off organs in the body providing an image so one can determine their structure and function.

Cardiac catheterization—A procedure in which dye is injected through a tube or catheter into an artery to more easily observe valves or blood vessels seen on an x ray.

Left ventricle—One of the lower chambers of the heart, which pumps blood to the aorta.

Murmur—An abnormal heart sound that can reflect a valve dysfunction.

Rheumatic fever—A bacterial infection that often causes heart inflammation.

Pulmonary valve—The valve located between the pulmonary artery and the right ventricle, which brings blood to the lungs.

An x ray can also reveal calcium deposits on the valve, as well as congestion in the lungs. **Echocardiography** can pick up thickening of the valve, heart size, and whether or not the valve is working properly. This is a procedure in which high frequency sound waves harmlessly bounce off organs in the body. **Cardiac catheterization**, in which a contrast dye is injected in an artery using a catheter, is the key tool to confirm stenosis and gauge its severity.

Treatment

Treatment depends on the symptoms and how the heart's function is affected. The valve can be opened without surgery by using a balloon catheter, but this is often a temporary solution. The procedure involves inserting a deflated balloon at the end of a catheter through the arteries to the valve. Inflating the balloon should widen the valve. In severe stenosis, **heart valve replacement** is recommended, most often involving open-heart surgery. The valve can be replaced with a mechanical valve, a valve from a pig, or by moving the patient's other heart valve (pulmonary) into the position of the aortic valve and then replacing the pulmonary valve with an mechanical one. Anyone with aortic stenosis needs to take **antibiotics** (amoxicillin, erythromycin, or clindamycin) before dental and some other surgical procedures, to prevent a heart valve infection.

Prognosis

The prognosis for aortic valve stenosis depends on the severity of the disease. With surgical repair, the disease is curable. Patients suffering mild stenosis can usually lead a normal life; a minority of the patients progress to severe disease. Anyone with moderate stenosis should avoid vigorous physical activity. Most of these patients end up suffering some kind of coronary **heart disease** over a 10 year period. Because it is a progressive disease, moderate and severe stenosis will be treated ultimately with surgery. Severe disease, if left untreated, leads to death within 2 to 4 years once the symptoms start.

Prevention

There is no way to prevent aortic stenosis.

Apgar testing

Definition

Apgar testing is an assessment of the newborn by rating color, heart rate, stimulus response, muscle tone, and respirations on a scale of zero to two in each category, for a maximum possible score of 10. It is performed twice, first at one minute and then again at five minutes after birth.

Description

The five areas (color, heart rate, stimulus response, muscle tone, and respirations) are scored as follows:

WWW.BOOKBAZ.IR

DR. VIRGINIA APGAR (1909–1974)

(AP Images.)

As one of very few female medical students at Columbia University College of Physicians and Surgeons in New York during the early 1930s and one of the first women to graduate from its medical school, Apgar knew that her goal of becoming a surgeon would not be achieved easily in a male-dominated profession. Reluctantly, she switched her medical specialty to anesthesiology and embraced her new field with typical intelligence and energy. At this time, anesthesiology was a relatively new field, having been left by the doctors mostly to the attention of nurses. Apgar realized immediately how much in need of scientifically trained personnel was this significant part of surgery, and she set out to make anesthesiology a separate medical discipline. By 1937, she had become the fiftieth physician to be certified as an anesthesiologist in the United States. The following year she was appointed director of anesthesiology at the Columbia-Presbyterian Medical Center, becoming the first woman to head a department at that institution.

As the attending anesthesiologist who assisted in the delivery of thousands of babies during these years, Apgar realized that infants had died from respiratory or circulatory complications which early treatment could have prevented. Apgar decided to bring her considerable research skills to this childbirth dilemma, and her careful study resulted in her publication of the Apgar Score System in 1952.

- Color or appearance: 2 if the skin is pink all over; 1 for acrocyanosis, where the trunk and head are pink, but the arms and legs are blue; and 0 if the whole body is blue. Newborns with naturally darker skin color will not be pink. However, pallor is still noticeable, especially in the soles and palms. Color is related to the neonate's ability to oxygenate its body and extremities and is dependent on heart rate and respirations. A perfectly healthy newborn will often receive a score of 9 because of some blueness in the hands and feet.
- heart rate (pulse): 2 for a pulse of 100+ beats per minute (bpm); 1 for a pulse below 100 bpm; 0 for no pulse. Heart rate is assessed by listening with a stethoscope to the newborn's heart and counting the number of beats.
- Stimulus response (grimace, or reflex irritability): 2 if the neonate coughs, sneezes, or vigorously cries in response to a stimulus (such as the use of nasal suctioning, stroking the back to assess for spinal abnormalities, or having the foot tapped); 1 for a slight cry or grimace in response to the stimulus; 0 for no response.
- Muscle tone (activity): 2 for vigorous movements of arms and legs; 1 for some movement; 0 for no movement, limpness.
- Respirations: 2 for visible breathing and crying; 1 for slow, weak, irregular breathing; 0 for apnea, or no breathing. A crying newborn can adequately oxygenate its lungs. Respirations are best assessed by watching the rise and fall of the neonate's abdomen, as infants are diaphragmatic breathers.

The combined first letters of appearance, pulse, grimace, activity, and respirations spell Apgar.

Purpose

Apgar scoring was originally developed in the 1950s by the anesthesiologist Virginia Apgar to assist practitioners attending a birth in deciding whether a newborn was in need of resuscitation. Using a scoring method fosters consistency and standardization among different practitioners. A February 2001 study published in the *New England Journal of Medicine* investigated whether Apgar scoring continues to be relevant. Researchers concluded that "The Apgar scoring system remains as relevant for the prediction of neonatal survival today as it was almost 50 years ago." However, a 2006 study published in the *Journal of Pediatrics* found that there was a wide variability of Apgar scores among observers.

KEY TERMS

Acrocyanosis—A slight cyanosis, or blueness, of the hands and feet of the neonate is considered normal. This impaired ability to fully oxygenate the extremities is due to an immature circulatory system which is still in flux.

Amniotic fluid—The protective fluid that surrounds the fetus while growing in the amniotic sac within the uterus.

Neonate—The term for the newborn infant, from birth until one month of age.

Neonatologist—A physician who specializes in problems of newborn infants.

Pallor—Extreme paleness in the color of the skin.

Benefits

The Apgar test is a quick determination of a newborn's health and alerts medical caregivers to whether the baby needs immediate medical intervention.

Preparation

No preparation is needed to perform the test. However, while being born the neonate may receive nasal and oral suctioning to remove mucus and amniotic fluid. This may be done when the head of the newborn is safely out, while the mother rests before she continues to push.

Aftercare

Since the test is primarily observational in nature, no aftercare is needed. However, the test may flag the need for immediate intervention or prolonged observation.

Results

The maximum possible score is 10, the minimum is zero. It is rare to receive a true 10, as some **acrocyanosis** in the newborn is considered normal, and therefore not a cause for concern. Most infants score between 7 and 10. These infants are expected to have an excellent outcome. A score of 4, 5, or 6 requires immediate intervention, usually in the form of oxygen and respiratory assistance, or perhaps just suctioning if breathing has been obstructed by mucus. While suctioning is being done, a source of oxygen may be placed near, but not over the newborn's nose and mouth. This form of oxygen is referred to as *blow-by*. A score in the 4–6 range indicates that the neonate is having some difficulty adapting to extrauterine life. This may be due to medications given to the mother during a difficult labor, or at the very end of labor, when these medications have an exaggerated effect on the neonate.

With a score of 0–3, the newborn is unresponsive, apneic, pale, limp, and may not have a pulse. Interventions to resuscitate will begin immediately. The test is repeated at five minutes after birth and both scores are documented. Should the resuscitation effort continue into the five-minute time period, interventions would not stop in order to perform the test. The one-minute score indicates the need for intervention at birth. It addresses survival and prevention of birth-related complications resulting from inadequate oxygen supply. Poor oxygenation may be due to inadequate neurological and/or chemical control of respiration. The five-minute score appears to have a more predictive value for morbidity and normal development, although research studies on this are inconsistent in their conclusions.

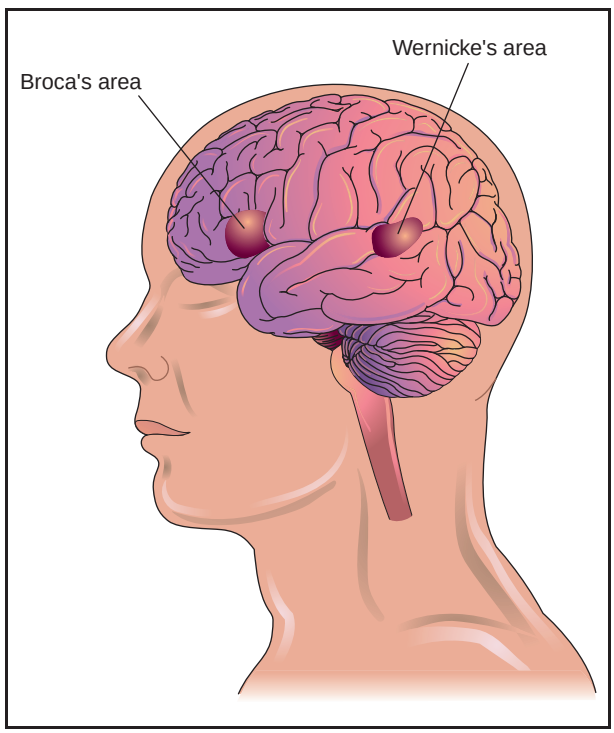
Aphasia

Definition

Aphasia is condition characterized by either partial or total loss of the ability to communicate verbally or using written words. A person with aphasia may have difficulty speaking, reading, writing, recognizing the names of objects, or understanding what other people have said. Aphasia is caused by a brain injury, as may occur during a traumatic accident or when the brain is deprived of oxygen during a **stroke**. It may also be caused by a **brain tumor**, a disease such as Alzheimer's, or an infection, like encephalitis. Aphasia may be temporary or permanent. Aphasia does not include speech impediments caused by loss of muscle control.

Description

To understand and use language effectively, an individual draws upon word memory—stored information on what certain words mean, how to put them together, and how and when to use them properly. For a majority of people, these and other language functions are located in the left side (hemisphere) of the brain. Damage to this side of the brain is most commonly linked to the development of aphasia. Interestingly, however, left-handed people appear to have language areas in both the left and right hemispheres of the brain and, as a result, may develop aphasia from damage to either side of the brain.



Broca's aphasia results from damage to the frontal lobe of the language-dominant area of the brain. Individuals with Broca's aphasia may become mute or only able to use single-word statements or speak full sentences, with great difficulty. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Stroke is the most common cause of aphasia in the United States. Approximately 500,000 individuals suffer strokes each year, and 20% of these individuals develop some type of aphasia. Other causes of brain damage include head injuries, brain tumors, and infection. About half of the people who show signs of aphasia have what is called temporary or transient aphasia and recover completely within a few days. An estimated one million Americans suffer from some form of permanent aphasia. As yet, no connection between aphasia and age, gender, or race has been found.

Aphasia is sometimes confused with other conditions that affect speech, such as dysarthria and **apraxia**. These condition affect the muscles used in speaking rather than language function itself. Dysarthria is a speech disturbance caused by lack of control over the muscles used in speaking, perhaps due to nerve damage. Speech apraxia is a speech disturbance in which language comprehension and muscle control are retained, but the memory of how to use the muscles to form words is not.

Causes and symptoms

Aphasia can develop after an individual sustains a brain injury from a stroke, head **trauma**, tumor, or infection, such as herpes encephalitis. As a result of this injury, the pathways for language comprehension or production are disrupted or destroyed. For most people, this means damage to the left hemisphere of the brain. (In 95–99% of right-handed people, language centers are in the left hemisphere, and up to 70% of left-handed people also have left-hemisphere language dominance.) According to the traditional classification scheme, each form of aphasia is caused by damage to a different part of the left hemisphere of the brain. This damage affects one or more of the basic language functions: speech, naming (the ability to identify an object, color, or other item with an appropriate word or term), repetition (the ability to repeat words, phrases, and sentences), hearing comprehension (the ability to understand spoken language),

KEY TERMS

Anomic aphasia—A condition characterized by either partial or total loss of the ability to recall the names of persons or things as a result of a stroke, head injury, brain tumor, or infection.

Broca's aphasia—A condition characterized by either partial or total loss of the ability to express oneself, either through speech or writing. Hearing comprehension is not affected. This condition may result from a stroke, head injury, brain tumor, or infection.

Computed tomography (CT)—An imaging technique that uses cross-sectional x rays of the body to create a three-dimensional image of the body's internal structures.

Conduction aphasia—A condition characterized by the inability to repeat words, sentences, or phrases as a result of a stroke, head injury, brain tumor, or infection.

Frontal lobe—The largest, most forward-facing part of each side or hemisphere of the brain.

Global aphasia—A condition characterized by either partial or total loss of the ability to communicate verbally or to use written words as a result of widespread injury to the language areas of the brain. This condition may be caused by a stroke, head injury, brain tumor, or infection. The exact language abilities affected vary depending on the location and extent of injury.

Hemisphere—One of the two halves or sides—the left and the right—of the brain.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Subcortical aphasia—A condition characterized by either partial or total loss of the ability to communicate verbally or using written words as a result of damage to non-language-dominated areas of the brain. This condition may be caused by a stroke, head injury, brain tumor, or infection.

Temporal lobe—The part of each side or hemisphere of the brain that is on the side of the head, nearest the ears.

Transcortical aphasia—A condition characterized by either partial or total loss of the ability to communicate verbally or using written words that does not affect an individual's ability to repeat words, phrases, and sentences.

Wernicke's aphasia—A condition characterized by either partial or total loss of the ability to understand what is being said or read. The individual maintains the ability to speak, but speech may contain unnecessary or made-up words.

reading (the ability to understand written words and their meaning), and writing (the ability to communicate and record events with text).

The traditional classification scheme includes eight types of aphasia:

- Broca's aphasia, also called motor aphasia, results from damage to the front portion or frontal lobe of the language-dominant area of the brain. Individuals with Broca's aphasia may be completely unable to use speech (mutism) or may be able to use single-word statements or even full sentences, though these sentences may require a great deal of effort to construct. Small words, such as conjunctions (and, or, but) and articles (the, an, a), may be omitted, leading to a "telegraph" quality in their speech. Hearing comprehension is usually not affected, so they are able to understand other people's speech and conversation and can follow commands. Often, they may experience weakness on the right side of their bodies, which can make it difficult to write. Reading ability is impaired, and they may have difficulty finding the right word when speaking. Individuals with Broca's aphasia may become frustrated and depressed because they are aware of their language difficulties.
- Wernicke's aphasia is caused by damage to the side portion or temporal lobe of the language-dominant area of the brain. Individuals with Wernicke's aphasia speak in long, uninterrupted sentences; however, the words used are frequently unnecessary or even made-up. They have a great deal of difficulty understanding other people's speech, sometimes to the point of being unable to understand spoken language at all. Reading ability is diminished, and although writing ability is retained, what is written may be abnormal. No physical symptoms, such as the

WWW.BOOKBAZ.IR

right-sided weakness seen with Broca's aphasia, are typically observed. Also, in contrast to Broca's aphasia, individuals with Wernicke's aphasia are not aware of their language errors.

- Global aphasia is caused by widespread damage to the language areas of the left hemisphere. As a result, all basic language functions are affected, but some areas may be more affected than others. For example, an individual may have difficulty speaking but may be able to write well. The individual may experience weakness and loss of feeling on the right side of their body.
- Conduction aphasia, also called associative aphasia, is rather uncommon. Individuals with conduction aphasia are unable to repeat words, sentences, and phrases. Speech is fairly unbroken, although individuals may frequently correct themselves and words may be skipped or repeated. Although able to understand spoken language, it may also be difficult for the individual with conduction aphasia to find the right word to describe a person or object. The impact of this condition on reading and writing ability varies. As with other types of aphasia, right-sided weakness or sensory loss may be present.
- Anomic or nominal aphasia primarily influences an individual's ability to find the right name for a person or object. As a result, an object may be described rather than named. Hearing comprehension, repetition, reading, and writing are not affected, other than by this inability to find the right name. Speech is fluent, except for pauses as the individual tries to recall the right name. Physical symptoms are variable, and some individuals have no symptoms of one-sided weakness or sensory loss.
- Transcortical aphasia is caused by damage to the language areas of the left hemisphere outside the primary language areas. There are three types of aphasia: transcortical motor aphasia, transcortical sensory aphasia, and mixed transcortical aphasia. All of the transcortical aphasias are distinguished from other types by the individual's ability to repeat words, phrases, or sentences. Other language functions may also be impaired to varying degrees, depending on the extent and particular location of brain damage.

As researchers continue to learn more about the brain's structure and function, new types of aphasia are being recognized. One newly recognized type of aphasia, subcortical aphasia, mimics the symptoms of other traditional types of aphasia but involves language disorders that are not typical. This type of aphasia is associated with injuries to areas of the brain typically not identified with language and language processing.

Diagnosis

Following brain injury, an initial bedside assessment is made to determine whether language function has been affected. If the individual experiences difficulty communicating, attempts are made to determine whether this difficulty arises from impaired language comprehension or an impaired ability to speak. A typical examination involves listening to spontaneous speech and evaluating the individual's ability to recognize and name objects, comprehend what is heard, and repeat sample words and phrases. The individual may also be asked to read text aloud and explain what the passage means. In addition, writing ability is evaluated by having the individual copy text, transcribe dictated text, and write something without prompting.

A speech pathologist or neuropsychologist may be asked to conduct more extensive examinations using in-depth, standardized tests. Commonly used tests include the Boston Diagnostic Aphasia Examination, the Western Aphasia Battery, and possibly, the Porch Index of Speech Ability.

The results of these tests indicate the severity of the aphasia and may also provide information regarding the exact location of the brain damage. This more extensive testing is also designed to provide the information necessary to design an individualized **speech therapy** program. Further information about the location of the damage is gained through the use of imaging technology, such as **magnetic resonance imaging** (MRI) and **computed tomography scans** (CT).

Treatment

Initially, the underlying cause of aphasia must be treated or stabilized. To regain language function, therapy must begin as soon as possible following the injury. Although there are no medical or surgical procedures currently available to treat this condition, aphasia resulting from stroke or **head injury** may improve through the use of speech therapy. For most individuals, however, the primary emphasis is placed on making the most of retained language abilities and learning to use other means of communication to compensate for lost language abilities.

Speech therapy is tailored to meet individual needs, but activities and tools that are frequently used include the following:

- Exercise and practice. Weakened muscles are exercised by repetitively speaking certain words or making facial expressions, such as smiling.
- Picture cards. Pictures of everyday objects are used to improve word recall and increase vocabulary. The names of the objects may also be repeated aloud as part of an exercise and practice routine.
- Picture boards. Pictures of everyday objects and activities are placed together, and the individual points to certain pictures to convey ideas and communicate with others.
- Workbooks. Reading and writing exercises are used to sharpen word recall and regain reading and writing abilities. Hearing comprehension is also redeveloped using these exercises.
- Computers. Computer software can be used to improve speech, reading, recall, and hearing comprehension by, for example, displaying pictures and having the individual find the right word.

Prognosis

The degree to which an individual can recover language abilities is highly dependent on how much brain damage occurred and the location and cause of the original brain injury. Other factors include the individual's age, general health, motivation and willingness to participate in speech therapy, and whether the individual is left or right handed. Language areas may be located in both the left and right hemispheres in left-handed individuals. Left-handed individuals are, therefore, more likely to develop aphasia following brain injury but, because they have two language centers, may recover more fully because language abilities can be recovered from either side of the brain. The intensity of therapy and the time between diagnosis and the start of therapy may also affect the eventual outcome.

Prevention

Because there is no way of knowing when a stroke, traumatic head injury, or disease will occur, very little can be done to prevent aphasia. The extent of recovery, however, in some cases, can be affected by an individual's willingness to cooperate and participate in speech therapy directly following the injury.

Aplastic anemia

Definition

Aplastic anemia is a disorder in which the bone marrow significantly decreases or stops production of blood cells.

Demographics

Yearly, aplastic anemia is diagnosed in about six out of every million people in the United States. Incidence of this disorder in Europe is similar to the U.S. incidence rate. More cases of aplastic anemia are observed in Asian countries, particularly in Japan, where the disorder is diagnosed in 14 people out of every million. This increased incidence rate is thought to be from environmental causes such as increased exposure to toxic chemicals rather than to genetics or heredity because Americans of Asian heritage do not have higher incidence rates than the general U.S. population

Aplastic anemia affects both males and females of all ages. There are two age groups that have an increased risk. Both young adults (20–25 years of age) and the elderly (over the age of 60) have higher rates of aplastic anemia than the general population.

Description

The bone marrow (soft tissue located within the hard outer shell of the bones) is responsible for the production of all types of blood cells. The mature forms of these cells include red blood cells, which carry oxygen throughout the body; white blood cells, which fight infection; and platelets, which are involved in clotting. In aplastic anemia, the basic structure of the marrow becomes abnormal, and those cells responsible for generating blood cells (hematopoietic cells) are greatly decreased in number or absent. These hematopoietic cells are replaced by large quantities of fat.

WWW.BOOKBAZ.IR

Risk factors

Eighty percent of cases of aplastic anemia are termed "acquired" cases because the cause can often be traced to a non genetic or non inherited cause such as:

- previous infection with viruses and bacteria such as a hepatitis virus, the Epstein-Barr virus, HIV, parovirus and mycobacteria
- exposure to toxic chemicals such as benzene
- radiation exposure
- exposure to the drugs chloramphenicol and phenylbutazone
- exposure to the element gold
- history of transfusional graft-versus-host disease (GVHD)
- history of liver transplant for fulminant hepatitis
- pregnancy in rare instances

Hereditary aplastic anemia is relatively rare (20% of cases) but occurs in Fanconi's anemia, Shwachman-Diamond syndrome, congenital dyskeratosis, and other rare congenital or inherited diseases.

Causes and symptoms

Aplastic anemia falls into three basic categories based on the origin of its cause: idiopathic, acquired, and hereditary.

Acquired aplastic anemia refers to cases where certain environmental factors and physical conditions seem to be associated with development of the disease. However, it is sometimes difficult to pinpoint the exact cause. About 80% of cases of aplastic anemia are considered to be acquired. Many clinicians believe aplastic anemia is an autoimmune disorder.

Symptoms of aplastic anemia tend to be the same as those of other **anemias**, including **fatigue**, weakness, tiny reddish-purple marks (petechiae) on the skin (evidence of pinpoint hemorrhages into the skin), evidence of abnormal bruising, and bleeding from the gums, nose, intestine, or vagina. The patient is likely to appear pale. If the anemia progresses, decreased oxygen circulating in the blood may lead to an increase in heart rate and the sudden appearance of a new heart murmur.

Diagnosis

Examination

During an office visit, a physician may suspect a form of anemia based on the patient's physical appearance and symptoms. A patient history is taken and exposure to any environmental toxins is noted. In order to confirm aplastic anemia, a blood draw is normally performed and additional testing is recommended as needed.

KEY TERMS

Autoimmune disease—A disease that occurs when the body's tissues and cells are attacked by the person's own immune system.

Bone marrow—A substance found in the cavities of bones, especially the long bones and the sternum (breast bone). The bone marrow contains those cells that are responsible for the production of the blood cells (red blood cells, white blood cells, and platelets).

Bone marrow transplant—A procedure in which a quantity of bone marrow is extracted through a needle from a donor, and then passed into a patient to replace the patient's diseased or absent bone marrow.

Hematopoietic cells—Those cells that are lodged within the bone marrow and are responsible for producing the cells that circulate in the blood (red blood cells, white blood cells, and platelets).

Immunosuppressive therapy—Treatment that suppresses the immune system's functioning.

Tests

A complete blood cell count (CBC) is performed on patients suspected of having anemia. This involves a simple blood draw, usually from the patient's arm. The blood is then analyzed at a lab. The blood count in aplastic anemia reveals low numbers of all formed blood cells. Red blood cells appear normal in size and coloration, but are greatly decreased in number. Cells called reticulocytes—very young red blood cells, which are usually produced in great numbers by the bone marrow in order to compensate for a severe anemia—are very low in number. Platelets and white blood cells are also decreased in number, though normal in structure.

Blood tests to determine histocompatibility with potential related donors for bone marrow transplant should be conducted early in the diagnostic process.

Radiographic imaging studies of the skeleton may be performed if there is suspicion of an inherited form of aplastic anemia since these conditions often cause skeletal abnormalities.

Procedures

A sample of the patient's bone marrow may need to be removed by needle (usually from the hip bone) and examined under a microscope. If aplastic anemia is present, this examination reveals very few or no hematopoietic cells and replacement with fat.

Treatment

Traditional

The first step in the treatment of aplastic anemia involves discontinuing exposure to any substance that may be causing the disorder. Although it would seem that blood transfusions would be helpful in this disease, in fact, they only serve as a temporary help and may complicate future attempts at **bone marrow transplantation**.

The most successful treatment for aplastic anemia is bone marrow transplantation. To do this, a marrow donor, preferably a human leukocyte antigen (HLA)-matched sibling, must be identified. There are a number of tissue markers that must be examined to determine whether a bone marrow donation is likely to be compatible with the patient's immune system. Compatibility is necessary to avoid complications, including the destruction of the donor marrow by the patient's own immune system.

Drugs

Infections are a great cause of concern in patients with aplastic anemia. The patient should be started on a course of broad spectrum **antibiotics** as soon as an infection is suspected. Patients with persistent **fever** may also be treated with antifungal medications.

Patients who cannot undergo bone marrow transplant can be treated with a number of agents, including antithymocyte globulin (ATG), cyclophosphamide, **steroids**, and cyclosporine. These agents all have the potential to cause a number of troublesome side-effects and may have a success rate of only 60–80%. Still, even among those patients who have a good response, many later have a relapse (return) of aplastic anemia. Researchers are trying to identify the molecules in certain stem cells that the immune system targets in aplastic anemia.

Prognosis

Aplastic anemia is a life-threatening illness. Without treatment, the condition is likely to be fatal. Survival depends on how severe the disease is at diagnosis, the type of treatment a patient is eligible for, and what kind of response their body has to that treatment.

Patients with a very low number of a particular type of white blood cell have a poor prognosis. They have an increased chance of dying from overwhelming bacterial infections. However, the estimated five-year survival rate for patients with aplastic anemia who have been treated with immunosuppressive therapy is 75%. Patients who undergo bone marrow transplantation using an HLA-matched sibling donor have a five-year survival rate greater than 90%.

Prevention

Since most cases of aplastic anemia can be linked to an identifiable cause, minimizing or eliminating exposure to the known causes of aplastic anemia should be strongly considered.

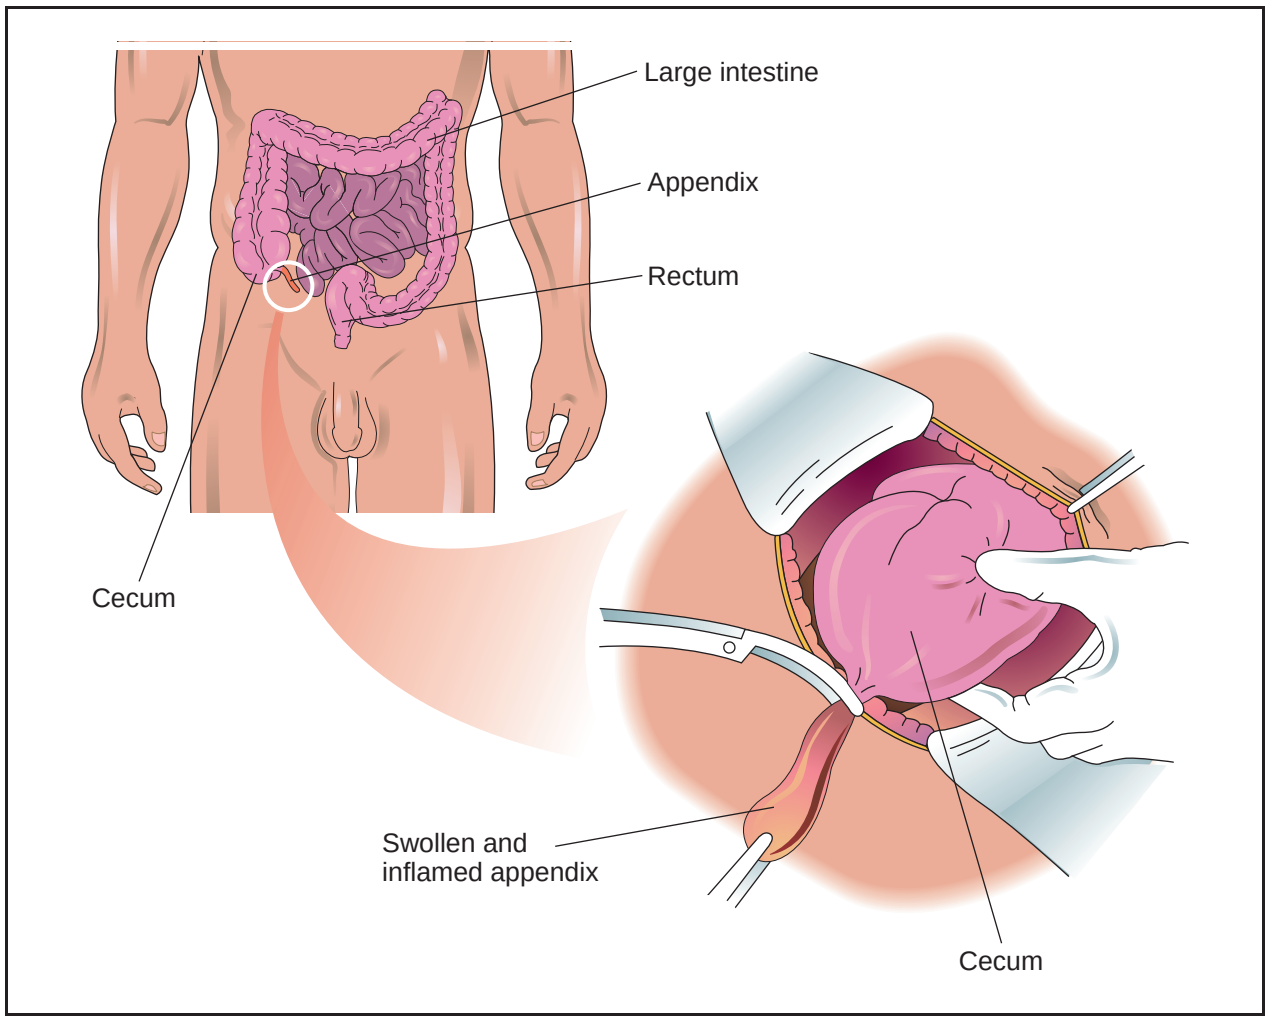
Appendectomy

Definition

Appendectomy is the surgical removal of the appendix. The appendix is a worm-shaped hollow pouch attached to the cecum, the beginning of the large intestine.

WWW.BOOKBAZ.IR



A traditional open appendectomy. After making an incision in the lower right section of the abdomen, the surgeon pulls the appendix up, separates it from the surrounding tissue and its attachment to the cecum, and then removes it. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Purpose

Appendectomies are performed to treat **appendicitis**, a condition characterized by an inflamed and infected appendix.

Description

An appendectomy is performed by a fully trained surgeon who, after medical school, has gone through years of training in an accredited residency program to learn the specialized skills of a surgeon. A sign of a surgeon's competence is certification by a national surgical board approved by the American Board of Medical Specialties (ABMS). All board-certified surgeons have completed an approved training program Aand have passed a rigorous specialty examination. The letters FACS (Fellow of the American College of Surgeons) after a surgeon's name are a further indication of a surgeon's qualifications.

Appendectomy is considered a major surgical operation. The surgeon must perform this operation in the operating room of a hospital. An anesthesiologist is present during the operation to administer an anesthetic.

AAfter the patient is anesthetized, the surgeon can remove the appendix either by using the traditional open procedure (in which a 2–3 in. [5–7.6 cm] incision is made in the abdomen) or via **laparoscopy**

(in which four 1 in. [2.5 cm] incisions are made in the abdomen).

Traditional open appendectomy

When the open approach is used, the surgeon makes an incision in the lower right section of the abdomen. Most incisions are less than 3 in. (7.6 cm) in length. The surgeon then identifies all of the organs in the abdomen and examines them for other diseases or abnormalities. The appendix is located and brought up into the opening. The surgeon separates the appendix from the surrounding tissue and its attachment to the cecum, and then removes it. The site where the appendix was previously attached, the cecum, is closed and returned to the abdomen. The muscle layers and then the skin are sewn back together.

Laparoscopic appendectomy

When the surgeon performs a laparoscopic appendectomy, four incisions, each about 1 in. (2.5 cm) in length, are made. One incision is near the umbilicus, or navel, and one is between the umbilicus and the pubis. Two smaller incisions are made on the right side of the lower abdomen. The surgeon passes a camera and special instruments through these incisions. With the aid of this equipment, the surgeon visually examines the abdominal organs and identifies the appendix. The appendix is then freed from all of its attachments and removed. The place where the appendix was formerly attached, the cecum, is stitched. The appendix is removed through one of the incisions. The instruments are removed and all of the incisions are closed.

Traditional vs. laparoscopic

Studies and opinions about the relative advantages and disadvantages of each method are divided. A skilled surgeon can perform either one of these procedures in less than one hour; however, laparoscopic appendectomy (LA) always takes longer than traditional appendectomy (TA). The increased time required to do an LA increases the patient's exposure to anesthetics and, therefore, the risk of complications. The longer procedure time makes LA more expensive than traditional surgery. Patients with either operation have similar **pain** medication needs, resume approved **diets** at comparable times, and stay in the hospital equivalent amounts of time. LA is of special benefit to women for whom diagnosis is difficult, as gynecological disease (such as **endometriosis**, **pelvic inflammatory disease**, ruptured ovarian follicles, ruptured **ovarian cysts**, and tubal pregnancies) may be the source of pain—not appendicitis. If LA is done in these patients, the pelvic organs can be more thoroughly examined and a definitive diagnosis made prior to removal of the appendix. Most surgeons select either TA or LA based on a patient's individual needs and circumstances.

Cost

Insurance plans do cover the costs of appendectomy. Fees are charged independently by the hospital and the physicians. Hospital charges include fees for operating and recovery room use and diagnostic and laboratory testing, as well as the normal hospital room charges. Surgical fees vary from region to region. The anesthesiologist's fee depends on the health of the patient and the length of the operation.

Preparation

Once the diagnosis of appendicitis is made and the decision has been made to perform an appendectomy, the patient undergoes the standard preparation for an operation. This usually takes only one to two hours and includes signing the operative consents, patient identification procedures, evaluation by the anesthesiologist, and moving the patient to the operating area of the hospital. Occasionally, if the patient has been ill for a prolonged period of time or has had protracted **vomiting**, a delay of several hours may be necessary to give the patient fluids and **antibiotics**.

Aftercare

Recovery from an appendectomy is similar to other operations. Patients are allowed to eat when the stomach and intestines begin to function again. Usually the first meal is a clear liquid diet—broth, juice, soda, and gelatin. If patients tolerate this meal, they can progress to a regular diet. Patients are asked to walk and resume their normal physical activities as soon as possible. If TA was done, work and physical education classes may be restricted for a full three weeks after the operation. If LA was done, most patients are able to return to work and strenuous activity within one to three weeks after the operation.

Risks

Certain risks are present when any operation is performed under general **anesthesia** and the abdominal cavity is opened. **Pneumonia** and collapse of the small airways (**atelectasis**) can occur. Patients who smoke are at a greater risk for developing these complications. **Thrombophlebitis**, or inflammation of the

WWW.BOOKBAZ.IR

veins, is rare but can occur if the patient requires prolonged bed rest. Bleeding can occur but rarely is a blood **transfusion** required. **Adhesions** (abnormal connections to abdominal organs by thin fibrous tissue) are a known complication of any abdominal surgery, including appendectomy. These can lead to intestinal obstruction and prevent the normal flow of intestinal contents. Hernias are a complication of any incision; however, they are rarely seen after appendectomy because the abdominal wall is very strong in the area of the standard appendectomy incision.

The overall complication rate of appendectomy depends upon the status of the appendix at the time it is removed. If the appendix has not ruptured, the complication rate is about 3%. If the appendix has ruptured, the complication rate rises to almost 59%. Wound infections do occur and are more common with rupture or if the appendicitis was severe or far advanced. An **abscess** may also form in the abdomen as a complication of appendicitis.

Occasionally, an appendix will rupture prior to its removal, spilling its contents into the abdominal cavity. **Peritonitis** or a generalized infection in the abdomen will occur. Treatment of peritonitis as a result of a ruptured appendix includes removal of what remains of the appendix, insertion of drains (rubber tubes that promote the flow of infection inside the abdomen to outside of the body), and antibiotics. **Fistula** formation (an abnormal connection between the cecum and the skin) rarely occurs. It is seen if the appendix has a broad attachment to the cecum and the appendicitis is far advanced, causing damage to the cecum.

The complications associated with undiagnosed, misdiagnosed, or delayed diagnosis of appendicitis are significant. This has led surgeons to perform an appendectomy any time that they feel appendicitis is the diagnosis. Most surgeons feel that in approximately 20% of their patients, a normal appendix will be removed. Rates much lower than this would seem to indicate that the diagnosis of appendicitis was being frequently missed.

Results

Most patients feel better immediately after an operation for appendicitis. Many patients are discharged from the hospital within 24 hours after the appendectomy. Others may require a longer stay, from three to five days. Almost all patients are back to their normal activities within three weeks.

KEY TERMS

Abscess—A collection of pus buried deep in the tissues or in a body cavity.

Anesthesia—A combination of drugs administered by a variety of techniques by trained professionals that provide sedation, amnesia, analgesia, and immobility adequate for the accomplishment of the surgical procedure with minimal discomfort to the patient.

Anesthesiologist—A physician who has special training and expertise in anesthesia techniques.

Cecum—The beginning of the large intestine and the place where the appendix attaches to the intestinal tract.

Pelvic organs—The organs inside of the body that are located within the confines of the pelvis. This includes the bladder and rectum in both sexes, and the uterus, ovaries, and fallopian tubes in females.

Peritonitis—Inflammation of the layer of tissue that lines the inside of the abdominal cavity.

Pubis—The front portion of the pelvis located in the anterior abdomen.

Thrombophlebitis—Inflammation of the veins, usually in the legs, which causes swelling and tenderness in the affected area.

Umbilicus—The navel.

Morbidity and mortality rates

The mortality rate of appendicitis has dramatically decreased over time. According to the Merck Manual, the mortality rate is estimated at less than 1% with timely surgery. Death is usually due to peritonitis, intra-abdominal abscess, or severe infection following rupture.

Alternatives

Appendectomies are usually carried out on an emergency basis to treat appendicitis. Due to the serious consequences of not removing an inflamed appendix, which include rupture and peritonitis, there are no alternatives to appendectomy.

An extracted appendix. *(© Lester V. Bergman/Corbis.)*

Appendicitis

Definition

Appendicitis is an inflammation of the appendix, which is the worm- or finger-shaped pouch attached to the cecum, the beginning of the large intestine. The appendix has no known function in the human body, but it can become diseased. Appendicitis is a medical emergency, and if it is left untreated the appendix may rupture and cause a potentially fatal infection.

Demographics

Appendicitis was the most common abdominal emergency in children and young adults in Canada and the United States as of 2010. The National Institutes of Health (NIH) estimates that about 7 percent of the general population will develop appendicitis at some point in life. There are on average about 1.1 cases per 1,000 people each year in North America. The disorder is most common in people between the ages of 10 and 30, but it can develop at any age. The incidence is highest among males aged 10–14, and among females aged 15–19. It is rare in the elderly and in children under the age of two. In a few cases, appendicitis has been diagnosed in newborn babies.

Appendicitis is equally common in persons of all races and ethnic groups. It is more common in men than in women, however; the male/female ratio is about 1.7:1. Although appendicitis is not hereditary, it does appear to be more common in some families; in 2009, a team of Australian researchers reported a possible link to chromosome 1p37.3.

About 1 person in every 100,000 is born without an appendix; there are a few rare cases of persons born with two.

Description

The average human appendix ranges in size from about 3 inches in length to 4 or 5 inches, but appendices as long as 11 inches have been recorded. The appendix

WWW.BOOKBAZ.IR

is longer in children than in adults, and shrinks still further in older adults. Appendicitis develops when the lumen (inner cavity) of the appendix is blocked. This blockage can be caused by a number of different objects ranging from intestinal parasites to thick mucus or fecal matter, or an infection. As the blockage progresses, the tissues of the appendix begin to die from lack of blood flow. They are then invaded by bacteria and form pus. If the condition is not treated, the appendix swells and eventually bursts, spreading the infection throughout the abdomen. This spread of infection and inflammation to the tissues lining the abdomen is called **peritonitis** and is a very dangerous condition.

The **pain** of appendicitis usually starts two to three days before the appendix gets to the point of bursting. The person typically notices a vague discomfort in the area underneath the navel (belly button). Over the next day the pain gets worse and moves downward toward the lower right portion of the abdomen near the right hip. The "classic" symptoms of appendicitis at this point are nausea, **vomiting**, low-grade **fever** (below 100.3°F), **constipation** or **diarrhea**, swelling of the abdomen, pain that is worsened by coughing or walking, and loss of appetite. Fewer than 50 percent of patients with appendicitis, however, have the full set of classic symptoms. Children and the elderly are often misdiagnosed because they have fewer of these symptoms; in particular, very young children may be misdiagnosed because they cannot explain or describe their symptoms. As a result, their treatment is often delayed. The appendix ruptures before surgery in about 270 out of every 1,000 cases; the risk of rupture is higher in children, pregnant women, and older adults.

Risk factors

There are no significant risk factors for appendicitis; it can develop in persons of either sex, in all age groups, and in all racial or ethnic groups. Some doctors, however, think that people with a history of intestinal parasites, those whose **diets** are very low in fiber, and those with Coxsackievirus B infection may have a slightly increased risk of developing appendicitis over their lifetimes.

Causes and symptoms

Causes

The basic cause of appendicitis is inflammation of the appendix resulting from an obstruction of some kind or an infection. The appendix can be blocked by an overgrowth of lymphoid tissue, food wastes, small pieces of hardened stool, worms or other parasites, **foreign objects**, or a cancerous tumor. It may also become inflamed as a result of **trauma** or infection, or as a complication of Crohn's disease.

The blocked appendix swells up with pus and mucus, shutting down the blood vessels that supply it with blood. As the tissues of the appendix die, bacteria from the intestine grow rapidly within it. If the infection is not stopped by surgical removal of the organ, the appendix will eventually burst and the bacteria inside it will spread to other parts of the abdomen. Signs of rupture include the presence of symptoms for more than 24 hours, a fever, a high **white blood cell count**, and a fast heart rate. Very rarely, the inflammation and symptoms of appendicitis may disappear but recur again later.

Symptoms

There is no single symptom that is unique to appendicitis, nor is there a "typical" group of symptoms that all patients experience. The following are the most common symptoms and the percentages of patients who report having them:

- Pain in the abdomen moving from the navel to the right lower part of the abdomen: 80%
- Nausea: 85%
- Fever: 60%
- Loss of appetite: 74%
- Diarrhea or constipation: 18%
- Symptoms lasting less than 48 hours: 80% (About 2 percent of patients, however, report pain in the abdomen lasting as long as 2 weeks.)
- A previous history of pain in the abdomen: 23%

The location of the pain may vary depending on the location of the appendix. In about half the population, the appendix is located behind the cecum rather than at its beginning, and in some people, it is located on the left side of the body.

Diagnosis

A physician, physician assistant, or nurse practitioner usually makes an initial diagnosis of appendicitis based on history, physical findings, and laboratory results. A laboratory technician may provide a test that confirms a diagnosis. A surgeon removes an appendix. Nurses assist by collecting data from the patient and family, monitoring vital signs and status of pain, and providing patient education about the diagnosis, surgery, and recovery.

A careful history-taking and **physical examination** is the best way to diagnose appendicitis. It is

KEY TERMS

Alvarado score—A ten-point scoring system used by doctors to evaluate the likelihood that a patient has acute appendicitis.

Antiemetic—A type of medication given to prevent or reduce nausea and vomiting.

Appendectomy—Surgical removal of the appendix.

Appendix (plural: appendices)—The finger-shaped pouch attached to the cecum, the beginning of the large intestine.

Laparotomy—A surgical incision into the abdomen, made between the ribs and the pelvis, that offers surgeons a view inside the abdominal cavity.

Lumen—The hollow interior of a tube-shaped organ such as the appendix.

Peritonitis—Inflammation of the peritoneum, membranes lining the abdominal pelvic wall.

Pus—A whitish-yellow material produced by the body in response to a bacterial infection. It consists of tissue fluid and dead white blood cells.

Ulceration—An abnormal change in tissue accompanied by the death of cells.

often difficult even for experienced physicians to distinguish the symptoms of appendicitis from those of other abdominal disorders. A physician should ask such questions as where the pain is centered, whether the pain has shifted, and where the pain began. The physician should press on the abdomen to judge the location of the pain and the degree of tenderness.

The diagnosis of appendicitis can be tricky and complicated. The typical sequence of symptoms is present in only 50% of cases. In the other half of cases, less typical patterns may be seen, especially in pregnant women, older people, and infants. In pregnant women, appendicitis is easily masked by the frequent occurrence of mild abdominal pain and nausea from other causes. Elderly people may feel less pain and tenderness than most individuals, thereby delaying diagnosis and treatment, and leading to rupture in 30% of cases. Infants and young children often have diarrhea, vomiting, and fever in addition to pain. Another factor that complicates diagnosis is the variation in size and location of the appendix in different people. In some patients the appendix is located on the left side of the body rather than the right, and in others the appendix is unusually long and extends from the right side toward the left side of the body.

Some doctors use a scoring system called the Alvarado score to assess the patient's likelihood of having appendicitis. The score is based on six clinical signs (fever, rebound tenderness, abdominal pain migrating to the lower right quadrant, nausea or vomiting, loss of appetite, and pain on pressure in the lower right quadrant) and two laboratory measurements of white blood cells (number and type of WBCs) in the patient's blood serum. Two factors are assigned two points each and the remaining six one point each, for a maximum total score of ten points. A score below 5 generally indicates that the patient does not have appendicitis, while a score of 7 or higher is considered strongly predictive of acute appendicitis.

Examination

In addition to taking the patient's temperature and asking about recent nausea or loss of appetite, the doctor may perform certain maneuvers during the physical examination when appendicitis is suspected. Patients with appendicitis typically feel what is called rebound tenderness (soreness) when the doctor first presses on the abdomen and then releases the pressure. The patient may also stiffen the muscles of the abdomen in response to pressure; this reaction is called guarding. In addition, the doctor may be able to feel that the abdomen itself is rigid. The doctor may move or rotate the patient's right leg or hip in order to test for unusual pain during this maneuver. This is called the psoas sign, named for two muscles involved in bending or rotating the hip. Rectal exams for both men and women may be performed in order to rule out other possible diagnoses.

Tests

Several different types of laboratory and imaging tests may be performed as part of the diagnostic workup:

- Blood test. A high white blood cell count indicates the presence of infection, and the presence of a large number of white blood cells called neutrophils is one of the signs evaluated in the Alvarado score.
- Imaging tests. These may include x rays, ultrasound, or computed tomography (CT) scans. The CT scan is the most commonly used imaging test to diagnose appendicitis, but x-ray studies can be useful for detecting foreign bodies or hardened stools that may be blocking the appendix. The use of imaging studies to diagnose appendicitis was increasingly controversial as of 2010, however, as many surgeons maintain that they increase the risk of perforation by delaying surgery, add to the total cost of the

WWW.BOOKBAZ.IR

procedure, and have a low rate of accuracy in distinguishing between healthy and infected appendices.
- Urine test. This test may be done to rule out kidney stones or a urinary tract infection.
- Pregnancy test. Women of childbearing age are tested for pregnancy to rule out the possibility of an ectopic pregnancy (one in which the fetus is growing in the Fallopian tubes, cervix, or abdomen rather than the uterus). The pain caused by an ectopic pregnancy resembles that of acute appendicitis, and the consequences of a missed diagnosis are potentially life-threatening.

In early 2010 a group of researchers in Colorado reported on a new possible diagnostic test for appendicitis that measures the levels of a protein called S100A8/A9 in the patient's blood serum. The biomarker appears to be more sensitive than WBC measurements in diagnosing acute appendicitis.

Procedures

Persons with a diagnosis of appendicitis are usually taken immediately to surgery, where a laparotomy (surgical exploration of the abdomen) is done to confirm the diagnosis. Often, the diagnosis is not certain until an operation is completed. To avoid a ruptured appendix, surgery may be recommended without delay if the symptoms point clearly to appendicitis. If the symptoms are not clear, surgery may be postponed until they progress enough to confirm a diagnosis.

When appendicitis is strongly suspected in a woman of child-bearing age, a diagnostic **laparoscopy** is sometimes recommended even after a **pregnancy** test to be sure that a gynecological problem such as a ruptured ovarian cyst is not causing the pain. In this procedure, a lighted viewing tube is inserted into the abdomen through a small incision around the navel.

A normal appendix is discovered in about 10–20% of patients who undergo laparotomy for suspected appendicitis. Sometimes the surgeon will remove a normal appendix as a safeguard against appendicitis in the future. During the surgery, another specific cause for the pain and symptoms of appendicitis is found for about 30% of these patients.

Treatment

The standard treatment for acute (sudden, severe) appendicitis is an **appendectomy**, surgery to remove the appendix. Because of the potential for a life-threatening ruptured appendix, persons suspected of having appendicitis are often taken to surgery before the diagnosis is certain.

Traditional

The surgeon can perform an appendectomy (surgical removal of the appendix) in several different ways. The oldest procedure is called an open appendectomy. The surgeon makes an incision (cut) between 2 and 4 inches in length on the lower right side of the abdomen. The appendix is removed from its location and the area is rinsed with sterile fluid to prevent further infection.

A newer and more commonly used technique is called a laparoscopic appendectomy. It requires much smaller incisions, only an inch or so long. The surgeon inserts a laparoscope, which is an instrument that allows the surgeon to see inside the abdomen, through one incision, and surgical instruments to remove the appendix through another small incision. If the surgeon finds that the infection has spread or that there are other complications, the operation may have to be completed as an open appendectomy; according to the American College of Surgeons, about 110 in every 1,000 laparoscopic procedures have to be completed as open appendectomies.

In March 2008, surgeons at a medical center in California successfully removed a woman's appendix through her vagina. The procedure is still considered experimental but allows female patients to recover more rapidly.

Drugs

In a few cases, if the doctor is not certain of the diagnosis, he or she may prescribe a course of **antibiotics** to see whether the patient's symptoms are caused by something other than an inflamed appendix and may not require surgery. Antibiotics are also given intravenously during and after surgery to reduce the risk of infection. Treatment with antibiotics is essential if the appendix has ruptured before surgery.

Patients who have not yet been evaluated by a surgeon should not be given pain relievers, as they may mask the underlying symptoms. After surgery, however, patients are given pain relievers and **antiemetics** (drugs to prevent **nausea and vomiting**) as needed. Patients may be given **narcotics** (opioids, most often morphine or oxycodone) for severe pain but are encouraged to use NSAIDs (naproxen or ibuprofen) as soon as possible, as narcotic pain relievers often cause constipation. Patients should not drive or drink alcohol for at least two days after returning home because drowsiness is another common side effect of opioids.

Prognosis

Most people do very well after an appendectomy if their appendix was removed before it ruptured; about 10 percent will have complications after surgery. The average hospital stay is between 1 and 3 days after the operation but full recovery at home may take 2–6 weeks before the patient can return to vigorous **exercise** or lifting heavy objects. Patients are usually advised to eat a light diet and drink plenty of fluids (8–10 glasses per day) during recovery at home.

The mortality rate for appendicitis in the United States is very low, between 0.2 and 0.8 percent of patients; most of these deaths are caused by complications of peritonitis rather than by the appendectomy itself. The rate of complications in appendicitis increases tenfold if the appendix bursts before surgery. There are higher rates of perforation and mortality among children and elderly persons.

Prevention

There is some evidence that people from cultures whose diets have a high level of fiber (the part of plants that is not digested) are less likely to develop appendicitis than those whose diets are low in fiber. It is thought that higher levels of fiber in the diet help the intestines push food along more efficiently, thus lowering the likelihood that the appendix will become blocked by fecal matter. Apart from increasing the amount of fiber in one's diet through eating more vegetables, however, there is no definitive way to predict or prevent appendicitis.

Appetite stimulant drugs

Definition

Appetite stimulant drugs are medicines used to increase the desire to eat.

Purpose

These drugs are sometimes used to treat people who are very elderly or have chronic, debilitating diseases like cancer or HIV/AIDS to stimulate them eat enough food to preserve their strength and keep from losing weight.

Description

Two drugs, megesterol (Megace) and dronabinol (Marinol) are FDA approved as appetite stimulants for people with **AIDS**. They are not approved for but are sometimes used to increase appetites in the elderly or those suffering from cancer or other chronic, debilitating conditions.

Megace is available in capsule and liquid form. Marinol is available as capsules.

Recommended dosage

Doses depend on the conditions being treated and the condition of patients at the time of treatment.

Precautions

Megestrol (Megace)

Megace is a hazardous agent with precautions for appropriate handling and disposal.

With prolonged use, this drug may lower the ability of the body to respond to **stress**. It may produce or worsen existing diabetes.

This drug should be used with caution by people who have had **blood clots** or emboli.

Dronabinol (Marinol)

This drug should be used with caution in patients with seizure disorders or liver diseases.

Marinol may increase the effects of sedative or tranquiling drugs.

Side effects

Megestrol (Megace)

Adverse effects include high blood pressure, chest **pain**, swelling of the feet and legs, **headache**, mood changes, lethargy, skin rash, nausea, **diarrhea**, abdominal pain, **constipation**, weakness, and **shortness of breath**.

Drabinol (Marinol)

This drug may cause flushing and **palpitations**, **dizziness**, giddiness, distorted thinking, confusion, lack of muscle coordination, nausea, **vomiting**, abdominal pain, and weakness.

Interactions

Megestrol (Megace)

This drug should not be used with dofetilide (Tikosyn), as fatal heart **arrhythmias** may occur.

Dronabinol (Marinol)

Alcohol will increase the effects of this drug on the mind and muscle coordination.

James Waun, MD, RPh

Applied kinesiology *see* **Kinesiology, applied**

Appetite suppressant drugs

Definition

Appetite suppressant drugs are medications that decrease desire for food, which can result in decreased calorie consumption and weight loss.

Purpose

Appetite suppressant drugs are intended to reduce a dieter's desire to eat so that the dieter consumes fewer calories and loses weight. They are intended to be used under doctor supervision and in combination with regular **exercise** and a healthy diet. These drugs are not intended for use by dieters trying to lose a few pounds for cosmetic purposes. They are not intended for rapid weight loss, but instead are intended to help the dieter lose weight slightly faster over months.

Appetite suppressant drugs are designed to be used by individuals who are obese or who have health conditions related to being overweight. Prescription appetite suppressants are only approved for dieters

with a **body mass index** (BMI) of 30 or more, or those with a BMI of 27 or more with a weight-related condition such as type 2 diabetes, metabolic syndrome, high blood pressure, or dyslipidemia (abnormal amount of fat in the blood).

Demographics

A study published in the *Journal of the American Medical Association* found that a quarter of men and nearly half of women report that they are trying to lose weight at any given time. While no specific statistics on appetite suppressant use exist, the sale of the drugs is a multibillion-dollar industry. Women are generally more likely to use appetite suppressants than men, as is true with most diet products.

Description

Appetite suppressants work by affecting chemicals in the brain that control feelings of hunger. While each drug works slightly differently, they generally work by increasing the availability of certain neurotransmitters, including dopamine, norepinephrine, or serotonin, in the brain. They do this either by increasing the secretion of the neurotransmitters or by inhibiting their reuptake, allowing them to be present in the brain for a longer time. Some drugs affect just one of these chemicals, and some affect more than one. The result of these changes in brain chemistry is that the dieter feels less hungry or more full and satisfied, hence the dieter eats fewer calories during the day.

Prescription drugs

Prescription appetite suppressants are drugs that are only available with a doctor's prescription and that have been shown in clinical tests to be safe and effective. Commonly prescribed appetite suppressants include:

- phentermine (Adipex, Qysmia). Pentermine is approved for use up to 12 weeks. Common side effects include irritability, nervousness, tiredness, increased blood pressure, sense of well-being, drowsiness, and depression.
- diethylpropion (Tenuate, Tenuate Dospan). Diethlpropion is approved for use up to 12 weeks. Common side effects include restlessness, headache, difficulty sleeping, nausea, vomiting, diarrhea, and constipation.
- phendimetrazine tartrate (Bontril, Melfiat, Obezine, Phendiet, Prelu-2). Phendimetrazine tartrate is approved for use up to 12 weeks. Common side effects include problems sleeping, nausea, vomiting, constipation, diarrhea, dizziness, and nervousness or irritability.
- lorcaserin hydrochloride (Belviq). Dieters should not continue taking this medication if they have not seen at least 5% of body weight lost in the first 12 weeks. The most common side effects found in individuals who do not have diabetes include headache, dry mouth, dizziness, constipation, and fatigue. In individuals who do have diabetes the most common side effects included headache, cough, back pain, and hypoglycemia (dangerously low blood sugar).

The specific dosages prescribed may differ depending on the weight of the dieter and the number of times per day the medication will be taken. As weight loss occurs, dieters should check with their doctor regularly to ensure the dosage does not need to be adjusted.

Over-the-counter drugs

A variety of over-the-counter drugs, herbs, and supplements have been promoted as appetite suppressants. Many include **caffeine** in high doses, which can be dangerous. Because herbs and supplements are not regulated by the Food and Drug Administration (FDA) in the same way as prescription drugs, serious side effects are sometimes not discovered until many people have been affected. For example, ephedra, an herbal stimulant made from the ma huang plant, was banned in 2004 because it was found to cause serious heart problems in some dieters. Common over-the-counter appetite suppressants include:

- Green tea extract. It is believed that green tea can act as an appetite suppressant without as much caffeine as many other appetite suppressant pills. It is believed to work by increasing the amount of heat produced by the body, which decreases appetite.
- *Hoodia*. *Hoodia* is a plant from Africa that is believed to decrease appetite by affecting the hypothalamus.
- *Garcinia cambogia*. This plant from India may act as an appetite suppressant by increasing the amount of the neurotransmitter serotonin in the brain.
- *Guarana*. This plant is available either as a berry or root, and is believed to act similarly to caffeine and to decrease appetite.
- Bee pollen. Bee pollen is often recommended as an appetite suppressant. It is believed that its phenylalanine content works to reduce desire to eat. However, other proponents of bee pollen recommend it as an appetite stimulant.

Benefits

When prescription appetite suppressants are used responsibly in conjunction with increased exercise and a healthy diet they can somewhat increase the speed

WWW.BOOKBAZ.IR

and amount of weight lost in some individuals. It is possible that this increased weight loss can provide a psychological as well as physical benefit that helps dieters stick to their diet for a longer period.

There are a wide variety of benefits from reaching and maintaining a healthy weight. Many doctors suggest that for very obese people even losing 5–10% of body weight can greatly improve health. Losing weight can help reduce the risk of type 2 diabetes, cardiovascular disease, **stroke**, **heart attack**, and even some types of cancer.

Precautions

Women who are pregnant, may become pregnant, or who are breast feeding should never use appetite suppressant drugs. The drugs should never be used by children under 12, and should only be used in older children with close physician supervision. Individuals taking certain drugs including selective serotonin reuptake inhibiters (SSRIs) and **monoamine oxidase inhibitors** (MAOIs) should talk to their doctor because of the possibility of serious **drug interactions**. Individuals with high blood pressure, **heart disease**, or **glaucoma** should not take appetite suppressants.

Over-the-counter appetite suppressants are not regulated by the FDA in the same way that prescription medications are. This means that these drugs may contain a variety of substances not identified on the label, or may contain different dosages than are listed on the label. Studies have found that many diet pills and supplements have inaccurate labels, which can seriously endanger consumer health and well-being.

Preparation

Anyone considering beginning to take an appetite suppressant, even one that does not require a prescription, should consult a doctor.

Aftercare

When taking an appetite suppressant dieters should exercise regularly and eat healthy foods. It is recommended that dieters check in with their doctor regularly to monitor progress and to check for possible side effects such as elevations in blood pressure. Dieters who successfully lose weight may need to have the dosage of other medications reduced.

Risks

The risks and some potentially dangerous side effects vary with individual appetite suppressant drugs and can be serious. These drugs should never be used for weight loss that is purely cosmetic, but instead should be used when the health benefits associated with weight loss are likely to outweigh the common side effects of the drugs.

Some common side effects include **dizziness**, **constipation**, **diarrhea** difficulty sleeping, nervousness, headaches, and stomach problems. Less common side effects include confusion, swelling in lower limbs, heart **palpitations**, difficulty breathing, and **fainting**.

Prescription and over-the-counter appetite suppressants can interact with prescription medications, herbal remedies, and supplements. These interactions are typically minor, but can be serious or even fatal in some cases. It is important for dieters to talk to their doctor or pharmacist before beginning to take any appetite suppressant, even an over-the-counter formulation that purports to be made of natural ingredients. Natural is not always equivalent to safe or healthful.

KEY TERMS

Dietary supplement—A product, such as a vitamin, mineral, herb, amino acid, or enzyme, that is intended to be consumed in addition to an individual's diet with the expectation that it will improve health.

Metabolic syndrome—A group of factors that raise the individual's risk of heart disease, diabetes, and stroke. These include a large waist line, high level of fats (triglycerides) in the blood, low HDL (good) cholesterol level, high blood pressure or taking drugs to lower blood pressure, and high fasting blood sugar level (or taking drugs to control fasting blood sugar levels).

Neurotransmitter—One of a group of chemicals secreted by a nerve cell (neuron) to carry a chemical message to another nerve cell, often as a way of transmitting a nerve impulse. Examples of neurotransmitters include acetylcholine, dopamine, serotonin, and norepinephrine.

Stroke—Irreversible damage to the brain caused by insufficient blood flow to the brain as the result of a blocked artery. Damage can include loss of speech or vision, paralysis, cognitive impairment, and death.

Type 2 diabetes—Formerly called adult-onset diabetes. In this form of diabetes, the pancreas either does not make enough insulin or cells become insulin resistant and do not use insulin efficiently.

Research and general acceptance

Prescription appetite suppressant drugs have been shown to be effective for short-term assistance of dieters who also have healthy **diets** and engage in regular exercise. For a prescription drug to be approved by the FDA for sale it has to have been shown to be both safe and effective in clinical trials. Prescription drugs that are approved by the FDA for sale as appetite suppressants have therefore met this qualification.

Supplements, herbal compounds, and other over-the-counter products do not have to meet these strict requirements of safety and effectiveness to be sold. Therefore, for the majority of these products there is no research showing that they are effective for promoting weight loss.

While prescription medications do have to meet strict safety requirements, this is not a guarantee that side effects will not be discovered. The diet drugs fenfluramine and phentermine (fen-phen) were removed from the market in 1997 after it was shown that the combination caused heart problems in a large portion of dieters who used it. The manufacturer of subutramine (Meridia) voluntarily discontinued the drug in 2010 after research revealed that it increased the risk of negative cardiovascular events such as heart attacks in individuals who were taking it.

While research does suggest that appetite suppressant drugs can help dieters for a short time, doctors and nutritionists agree that there is no substitute for eating a healthy diet that includes a wide variety of fruits, vegetables, and whole grains, and getting regular moderate-intensity exercise.

Apraxia

Definition

Apraxia is neurological condition characterized by loss of the ability to perform activities that a person is physically able and willing to do.

Description

Apraxia is caused by brain damage related to conditions such as **head injury**, **stroke**, **brain tumor**, and Alzheimer's disease. The damage affects the brain's ability to correctly signal instructions to the body. Forms of apraxia include the inability to say some words or make gestures.

Various conditions cause apraxia, and it can affect people of all ages. A baby might be born with the condition. A car accident or fall that resulted in head **trauma** could lead to apraxia.

From 500,000 to 750,000 people need to be hospitalized each year for head injuries according to the American Medical Association (AMA). Men between the ages of 18 and 24 form the largest group of people with head injuries. While not all severe injuries result in apraxia, men in that age group are at risk.

WWW.BOOKBAZ.IR

KEY TERMS

Computer tomography (CT) scanning—A diagnostic imaging tool that uses x rays sent through the body at different angles.

Magnetic resonance imaging (MRI)—A diagnostic imaging tool that utilizes an electromagnetic field and radio waves.

Risk factors for strokes include high blood pressure, diabetes, and **heart disease**. Cigarette **smoking** also puts a person at risk for a stroke. Brain tumors are abnormal tissue growths in the skull. They may be secondary tumors caused by the spread of cancer through the body.

There is more than one type of apraxia, and a person may have one or more form of this condition. A milder form of apraxia is called dyspraxia.

Causes and symptoms

Apraxia is caused by conditions that affect parts of the brain that control movements. Apraxia is a result of damage to the brain's cerebral hemispheres. These are the two halves of the cerebrum and are the location of brain activities such as voluntary movements.

Apraxia causes a lapse in carrying out movements that a person knows how to do, is physically able to perform, and wants to do. A person may be willing and able to do something like bathe. However, the brain does not send the signals that allow the person to perform the necessary sequence of activities to do this correctly.

Types of apraxia

There are several types of apraxia, and a patient could be diagnosed with one or more forms of this condition. The types of apraxia include:

- Buccofacial or orofacial apraxia is the inability of a person to follow through on commands involving face and lip motions. These activities include coughing, licking the lips, whistling, and winking. Also known as facial-oral apraxia, it is the most common form of apraxia, according to the National Institute of Neurological Disorders and Stroke (NINDS).
- Limb-kinetic apraxia is the inability to make precise movements with an arm or leg.
- Ideomotor apraxia is the inability to make the proper movement in response to a command to pantomime an activity like waving.
- Constructional apraxia is the inability to copy, draw, or build simple figures.
- Ideational apraxia is the inability to do an activity that involves performing a series of movements in a sequence. A person with this condition could have trouble dressing, eating, or bathing. It is also known as conceptual apraxia.
- Oculomotor apraxia is characterized by difficulty moving the eyes.
- Verbal apraxia is a condition involving difficulty coordinating mouth and speech movements. It is referred to as apraxia of speech by organizations including the American Speech Language Hearing Association (ASHA).

A baby who does not coo or babble may display a symptom of apraxia of speech, according to ASHA. A young child may only say a few consonant sounds, and an older child may have difficulty imitating speech. An adult also has this difficulty. Other symptoms include saying the wrong words. A person wants to say "kitchen," but says "bipem" instead, according to an ASHA report.

A person diagnosed with apraxia may also have **aphasia**, a condition caused by damage to the brain's speech centers. This results in difficulty reading, witting, speaking, and understanding when others speak.

Post-apraxia changes

A person with apraxia could experience frustration about difficulty communicating or trouble performing tasks. In some cases, the condition could affect the person's ability to live independently.

Diagnosis

Diagnosis of apraxia could begin with testing of its underlying cause. Testing for conditions like a stroke or cancer includes the MRI (**magnetic resonance imaging**) and CT scanning (computer tomography scanning). A **brain biopsy** is used to measure changes caused by Alzheimer's disease. In all cases, the physician takes a family history. Head trauma that could cause apraxia is first treated in the emergency room.

Other diagnostic treatment is related to identifying the type of apraxia. For example, the physician may ask the patient to demonstrate how to blow out a candle, wave, use a fork, or use a toothbrush.

Assessment for speech apraxia in children includes a hearing evaluation to determine if difficulty in speaking is related to a **hearing loss**. If the condition appears related to apraxia, a speech-language pathologist examines muscle development in the jaw, lips, and tongue. The examination of adults and children includes an evaluation of how words are pronounced individually and in conversation. The pathologist observes how the patient breathes when speaking and the ability to perform actions like smiling.

The costs of diagnosis vary because the process could include examinations and diagnostic screening related to the underlying cost of the apraxia. Insurance generally covers part of these costs.

Treatment

The treatment for apraxia usually involves **rehabilitation** through speech-language therapy, **physical therapy**, or **occupational therapy**. In addition, treatment such as **chemotherapy** is administered for the condition that caused the apraxia.

Family education is an important component of apraxia treatment. The rehabilitation process takes time, and relatives can offer encouragement and support to the patient. They may be asked to help the patient with in-home exercises. Furthermore, family members sometimes need to take on the role of caregivers.

Speech-language therapy

Speech-language therapy focuses on helping the patients learn or regain communication skills. Therapists teach exercises to strengthen facial muscles used in speech. Other exercises concentrate on patients learning to correctly pronounce sounds and then turn those sounds into words.

In cases where apraxia limits the ability to speak, therapists help patients develop alternate means of communication. These alternatives range from gesturing to using a portable computer that writes and produces speech, according to ASHA.

Occupational and physical therapies

Occupational and physical therapies focus on helping patients regain the skills impaired by apraxia. Physical therapy exercises concentrate on areas such as mobility and balance. Occupational therapy helps patients relearn daily living skills.

Treatment costs

The costs of therapy vary by the type of treatment, regional location, and where the therapy is offered. Fees can range for $40 per hour for in-office **speech therapy** for a child to $85 per hour for in-home physical or occupational therapy for a senior citizen. Part of therapy costs may be covered by insurance.

Alternatives

Most alternative treatments target Alzheimer's disease and other conditions that cause apraxia. Herbal remedies thought to help people with Alzheimer's include **ginkgo biloba**, a plant extract. However, organizations including the Alzheimer's Association caution that the effectiveness and safety of this herbal remedy has not been evaluated by the U.S. Food and Drug Administration. The government does not require a review of supplements like ginkgo. Furthermore, there is a risk of internal bleeding if ginkgo is taken in combination with **aspirin** and blood-thinning medications.

Prognosis

The prognosis for apraxia depends on factors such as what caused the condition. While Alzheimer's is a degenerative condition, a child with verbal apraxia or a stroke patient could make progress.

In some cases, treatment helps a person to relearn or acquire skills needed to function. A caregiver may be required, and some people with **dementia** require supervised, long-term care.

Prevention

The methods of preventing apraxia focus on preventing the underlying causes of this condition. This may not be entirely possible when there is a family history of conditions such as stroke, dementia, and cancer. However, individuals lower their risk by not smoking and by exercising and eating a diet based on the American Heart Association guidelines.

Head injury can be prevented by wearing a helmet when participating in sports and bicycling. Wearing a seatbelt when in a vehicle also helps reduce the risk of head injury.

Aromatherapy

Definition

Aromatherapy is the therapeutic use of plant-derived, aromatic essential oils to promote physical and psychological well-being. It is sometimes used in combination with massage and other therapeutic techniques as part of a holistic treatment approach.

Purpose

Aromatherapy offers diverse physical and psychological benefits, depending on the essential oil or oil combination and method of application used. Some common medicinal properties of essential oils used in aromatherapy include: analgesic, antimicrobial, antiseptic, anti-inflammatory, astringent, antispasmodic, expectorant, diuretic, and sedative. Essential oils are used to treat a wide range of symptoms and conditions, including, but not limited to, gastrointestinal discomfort, skin conditions, menstrual **pain** and irregularities, stress-related conditions, **mood disorders**, circulatory problems, respiratory infections, and **wounds**.

Description

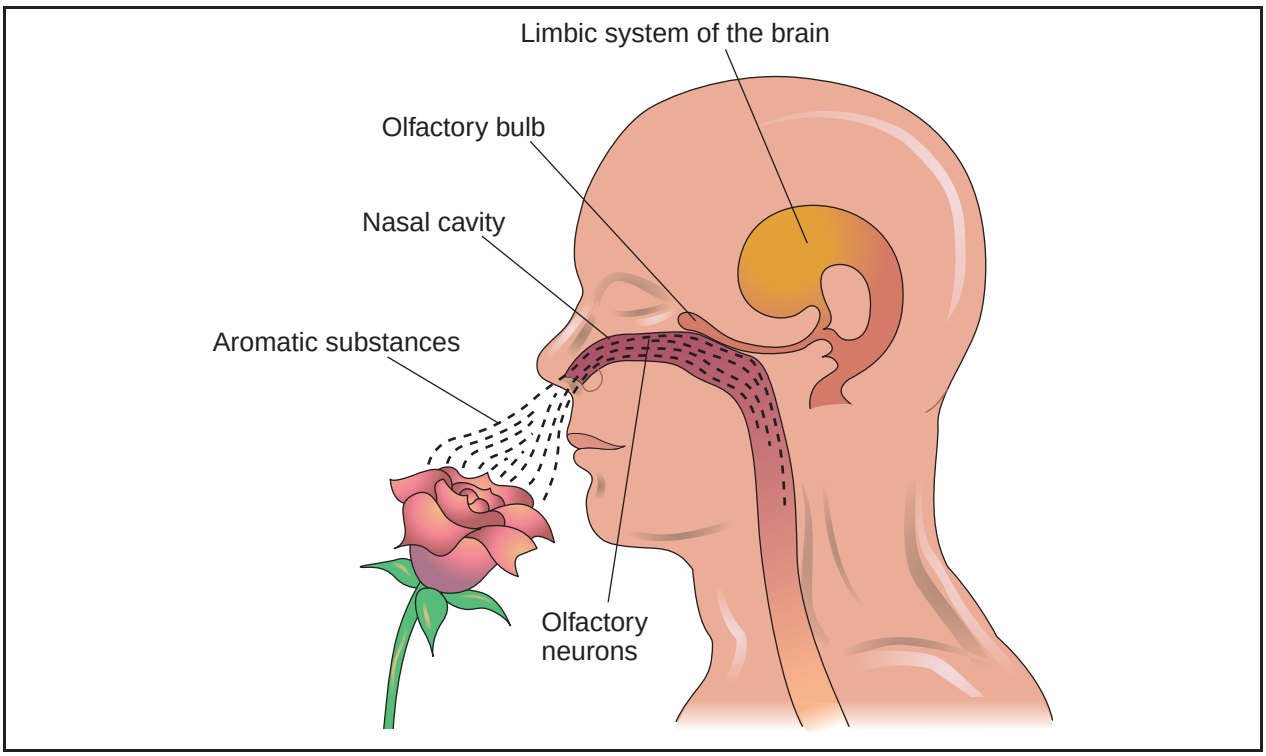
Origins

Aromatic plants have been employed for their healing, preservative, and pleasurable qualities throughout recorded history in both the East and West. As early as 1500 B.C. the ancient Egyptians used waters, oils, incense, resins, and ointments scented with botanicals for their religious ceremonies.

There is evidence that the Chinese may have recognized the benefits of herbal and aromatic remedies much earlier than this. The oldest known herbal text, Shen Nung's *Pen Ts'ao* (c. 2700-3000 B.C.) catalogs over 200 botanicals. Ayurveda, a practice of traditional Indian medicine that dates back over 2,500 years, also used aromatic herbs for treatment.

The Romans were well-known for their use of fragrances. They bathed with botanicals and integrated them into their state and religious rituals. So did the Greeks, with a growing awareness of the medicinal properties of herbs, as well. Greek physician and surgeon Pedanios Dioscorides, whose renown herbal text *De Materia Medica* (60 A.D.) was the standard textbook for Western medicine for 1,500 years, wrote extensively on the medicinal value of botanical aromatics. The *Medica* contained detailed information on over 500 plants and 4,740 separate medicinal uses for them, including an entire section on aromatics.

Written records of herbal distillation are found as early as the first century A.D., and around 1000 A.D., the noted Arab physician and naturalist Avicenna described the distillation of rose oil from rose petals, and the medicinal properties of essential oils in his writings. However, it wasn't until 1937, when French chemist René-Maurice Gattefossé published



As a holistic therapy, aromatherapy is believed to benefit both the mind and body. Here, the aromatic substances from a flower stimulate the olfactory bulb and neurons. The desired emotional response (such as relaxation) is activated from the limbic system. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Aromatherapie: Les Huiles essentielles, hormones végé tales, that aromatherapie, or aromatherapy, was introduced in Europe as a medical discipline. Gattefossé, who was employed by a French perfumeur, discovered the healing properties of lavender oil quite by accident when he suffered a severe burn while working and used the closest available liquid, lavender oil, to soak it in.

In the late twentieth century, French physician Jean Valnet used botanical aromatics as a front line treatment for wounded soldiers in World War II. He wrote about his use of essential oils and their healing and antiseptic properties, in his 1964 book *Aromatherapie, traitement des maladies par les essences des plantes*, which popularized the use of essential oils for medical and psychiatric treatment throughout France. Later, French biochemist Mauguerite Maury popularized the cosmetic benefits of essential oils, and in 1977 Robert Tisserand wrote the first English language book on the subject, *The Art of Aromatherapy*, which introduced massage as an adjunct treatment to aromatherapy and sparked its popularity in the United Kingdom.

In aromatherapy, essential oils are carefully selected for their medicinal properties. As essential oils are absorbed into the bloodstream through application to the skin or inhalation, their active components trigger certain pharmalogical effects (e.g., pain relief).

In addition to physical benefits, aromatherapy has strong psychological benefits. The volatility of an oil, or the speed at which it evaporates in open air, is thought to be linked to the specific psychological effect of an oil. As a rule of thumb, oils that evaporate quickly are considered emotionally uplifting, while slowly-evaporating oils are thought to have a calming effect.

Essential oils commonly used in aromatherapy treatment include:

- Roman chamomile (*Chamaemelum nobilis*). An anti-inflammatory and analgesic. Useful in treating otitis media (earache), skin conditions, menstrual pains, and depression.
- Clary sage (*Salvia sclarea*). This natural astringent is not only used to treat oily hair and skin, but is also said to be useful in regulating the menstrual cycle, improving mood, and controlling high blood pressure. Clary sage should not be used by pregnant women.

WWW.BOOKBAZ.IR

KEY TERMS

Antiseptic—Inhibits the growth of microorganisms.

Bactericidal—An agent that destroys bacteria (e.g., *Staphylococci aureus, Streptococci pneumoniae, Escherichia coli, Salmonella enteritidis*).

Carrier oil—An oil used to dilute essential oils for use in massage and other skin care applications.

Contact dermatitis—Skin irritation as a result of contact with a foreign substance.

Essential oil—A volatile oil extracted from the leaves, fruit, flowers, roots, or other components of a plant and used in aromatherapy, perfumes, and foods and beverages.

Holistic—A practice of medicine that focuses on the whole patient, and addresses the social, emotional, and spiritual needs of a patient as well as their physical treatment.

Phototoxic—Causes a harmful skin reaction when exposed to sunlight.

Remedy antidote—Certain foods, beverages, prescription medications, aromatic compounds, and other environmental elements that counteract the efficacy of homeopathic remedies.

Steam distillation—A process of extracting essential oils from plant products through a heating and evaporation process.

Volatile—Describes a substance that vaporizes or evaporates quickly when exposed to air.

- Lavender (*Lavandula officinalis*). A popular aromatherapy oil which mixes well with most essential oils, lavender has a wide range of medicinal and cosmetic applications, including treatment of insect bites, burns, respiratory infections, intestinal discomfort, nausea, migraine, insomnia, depression, and stress.
- Myrtle (*Myrtus communis*). Myrtle is a fungicide, disinfectant, and antibacterial. It is often used in steam aromatherapy treatments to alleviate the symptoms of whooping cough, bronchitis, and other respiratory infections.
- Neroli (bitter orange), (*Citrus aurantium*). Citrus oil extracted from bitter orange flower and peel and used to treat sore throat, insomnia, and stress and anxiety-related conditions.
- Sweet orange (*Citrus sinensis*). An essential oil used to treat stomach complaints and known for its reported ability to lift the mood while relieving stress.
- Peppermint (*Mentha piperita*). Relaxes and soothes the stomach muscles and gastrointestinal tract. Peppermint's actions as an anti-inflammatory, antiseptic, and antimicrobial also make it an effective skin treatment, and useful in fighting cold and flu symptoms.
- Rosemary (*Rosmarinus officinalis*). Stimulating essential oil used to treat muscular and rheumatic complaints, as well as low blood pressure, gastrointestinal problems, and headaches.
- Tea tree (*Melaleuca alternifolia*). Has bactericidal, virucidal, fungicidal, and anti-inflammatory properties that make it a good choice for fighting infection. It is recommended for treating sore throat and respiratory infections, vaginal and bladder infections, wounds, and a variety of skin conditions.
- Ylang ylang (*Cananga odorata*). A sedative essential oil sometimes used to treat hypertension and tachycardia.

Essential oils contain active agents that can have potent physical effects. While some basic aromatherapy home treatments can be self-administered, medical aromatherapy should always be performed under the guidance of an aromatherapist, herbalist, massage therapist, nurse, or physician.

Inhalation

The most basic method of administering aromatherapy is direct or indirect inhalation of essential oils. Several drops of an essential oil can be applied to a tissue or handkerchief and gently inhaled. A small amount of essential oil can also be added to a bowl of hot water and used as a steam treatment. This technique is recommended when aromatherapy is used to treat respiratory and/or skin conditions. Aromatherapy steam devices are also available commercially. A warm bath containing essential oils can have the same effect as steam aromatherapy, with the added benefit of promoting relaxation. When used in a bath, water should be lukewarm rather than hot to slow the evaporation of the oil.

Essential oil diffusers, vaporizers, and light bulb rings can be used to disperse essential oils over a large area. These devices can be particularly effective in aromatherapy that uses essential oils to promote a healthier home environment. For example, eucalyptus and tea tree oil are known for their antiseptic qualities and are frequently used to disinfect sickrooms, and citronella and geranium can be useful in repelling insects.

Examples of aromatherapy oils

Name	Description	Conditions treated
Bay laurel	Antiseptic, diuretic, sedative, etc.	Bronchitis, common cold, digestive problems, influenza, and scabies and lice (CAUTION: Don't use if pregnant.)
Chamomile	Anti-inflammatory, antiseptic, pain reliever, and sedative	Acne, arthritis, burns, digestive problems, hay fever, menstrual and menopausal symptoms, and sunburn.
Clary sage	Anticonvulsive, anti-inflammatory, antiseptic, and relaxant	Anxiety, burns, eczema, and menstrual and menopausal symptoms (CAUTION: Don't use if pregnant.)
Eucalyptus	Analgesic, antibacterial, antiseptic, astringent, and expectorant	Boils, breakouts, common cold, cough, influenza, and sinusitis (CAUTION: Not to be taken orally.)
Lavender	Analgesic, antiseptic, calming/soothing	Depression, headache, insomnia, nausea, sprains, and stress
Peppermint	Pain reliever	Headache, indigestion, motion sickness, muscle pain, and nausea
Rosemary	Antiseptic, diuretic, and stimulant	Bronchitis, fluid retention, gas, indigestion, and influenza (CAUTION: Don't use if pregnant or have epilepsy or hypertension.)
Tarragon	Antispasmodic, diuretic, laxative, and stimulant	Gas, indigestion, and menstrual and menopausal symptoms (CAUTION: Don't use if pregnant.)
Tea tree	Antiseptic and soothing	Abscesses, acne, bronchitis, burns, common cold, and vaginitis
Thyme	Antibacterial, antiseptic, antispasmodic, and stimulant	Cough, diarrhea, gas, intestinal worms, laryngitis (CAUTION: Don't use if pregnant or have hypertension.)

(Table by PreMediaGlobal. © Cengage Learning®.)

Direct application

Because of their potency, essential oils are diluted in a carrier oil or lotion before being applied to the skin to prevent an allergic skin reaction. The carrier oil can be a vegetable or olive based one, such as wheat germ or avocado. Light oils, such as safflower, sweet almond, grapeseed, hazelnut, apricot seed, or peach kernel, may be absorbed more easily by the skin. Standard dilutions of essential oils in carrier oils range from 2–10%. However, some oils can be used at higher concentrations, and others should be diluted further for safe and effective use. The type of carrier oil used and the therapeutic use of the application may also influence how the essential oil is mixed. Individuals should seek guidance from a healthcare professional and/or aromatherapist when diluting essential oils.

Massage is a common therapeutic technique used in conjunction with aromatherapy to both relax the body and thoroughly administer the essential oil treatment. Essential oils can also be used in hot or cold compresses and soaks to treat muscle aches and pains (e.g., lavender and ginger). As a **sore throat** remedy, antiseptic and soothing essential oils (e.g., tea tree and sage) can be thoroughly mixed with water and used as a gargle or mouthwash.

Internal use

Some essential oils can be administered internally in tincture, infusion, or suppository form to treat certain symptoms or conditions; however, this treatment should never be self-administered. Essential oils should only be taken internally under the supervision of a qualified healthcare professional.

As non prescription botanical preparations, the essential oils used in aromatherapy are typically not paid for by health insurance. The self-administered nature of the therapy controls costs to some degree. Aromatherapy treatment sessions from a professional aromatherapist are not covered by health insurance in most cases, although aromatherapy performed in conjunction with **physical therapy**, nursing, therapeutic massage, or other covered medical services may be. Individuals should check with their insurance provider to find out about their specific coverage.

The adage "You get what you pay for" usually applies when purchasing essential oils, as bargain oils are often adulterated, diluted, or synthetic. Pure essential oils can be expensive; and the cost of an oil will vary depending on its quality and availability.

Preparations

The method of extracting an essential oil varies by plant type. Common methods include water or steam distillation and cold pressing. Quality essential oils should be unadulterated and extracted from pure botanicals. Many aromatherapy oils on the market are synthetic and/or diluted, contain solvents, or are extracted from botanicals grown with pesticides or

WWW.BOOKBAZ.IR

herbicides. To ensure best results, essential oils should be made from pure organic botanicals and labeled by their full botanical name. Oils should always be stored dark bottles out of direct light.

Before using essential oils on the skin, individuals should perform a skin patch test by applying a small amount of the diluted oil behind the wrist and covering it with a bandage or cloth for up to 12 hours. If redness or irritation occurs, the oil should be diluted further and a second skin test performed, or it should be avoided altogether. Individuals should never apply undiluted essential oils to the skin unless advised to do so by a trained healthcare professional.

Precautions

Individuals should only take essential oils internally under the guidance and close supervision of a health-care professional. Some oils, such as eucalyptus, wormwood, and sage, should never be taken internally. Many essential oils are highly toxic and should never be used at all in aromatherapy. These include (but are not limited to) bitter almond, pennyroyal, mustard, sassafras, rue, and mugwort.

Citrus-based essential oils, including bitter and sweet orange, lime, lemon, grapefruit, and tangerine, are phototoxic, and exposure to direct sunlight should be avoided for at least four hours after their application.

Other essential oils, such as cinnamon leaf, black pepper, juniper, lemon, white camphor, eucalyptus blue gum, ginger, peppermint, pine needle, and thyme can be extremely irritating to the skin if applied in high enough concentration or without a carrier oil or lotion. Caution should always be exercised when applying essential oils topically. Individuals should never apply undiluted essential oils to the skin unless directed to do so by a trained healthcare professional and/or aromatherapist.

Individuals taking homeopathic remedies should avoid black pepper, camphor, eucalyptus, and peppermint essential oils. These oils may act as a remedy antidote to the homeopathic treatment.

Children should only receive aromatherapy treatment under the guidance of a trained aromatherapist or healthcare professional. Some essential oils may not be appropriate for treating children, or may require additional dilution before use on children.

Certain essential oils should not be used by pregnant or nursing women or by people with specific illnesses or physical conditions. Individuals suffering from any chronic or acute health condition should inform their healthcare provider before starting treatment with any essential oil.

Asthmatic individuals should not use steam inhalation for aromatherapy, as it can aggravate their condition.

Essential oils are flammable, and should be kept away from heat sources.

Side effects

Side effects vary by the type of essential oil used. Citrus-based essential oils can cause heightened sensitivity to sunlight. Essential oils may also cause **contact dermatitis**, an allergic reaction characterized by redness and irritation. Anyone experiencing an allergic reaction to an essential oil should discontinue its use and contact their healthcare professional for further guidance. Individuals should do a small skin patch test with new essential oils before using them extensively.

Research and general acceptance

The antiseptic and bactericidal qualities of some essential oils (such as tea tree and peppermint) and their value in fighting infection has been detailed extensively in both ancient and modern medical literature.

Recent research in mainstream medical literature has also shown that aromatherapy has a positive psychological impact on patients, as well. Several clinical studies involving both post-operative and chronically ill subjects showed that massage with essential oils can be helpful in improving emotional well-being, and consequently, promoting the healing process.

The use of holistic aromatherapy is widely accepted in Europe, particularly in Great Britain, where it is commonly used in conjunction with massage as both a psychological and physiological healing tool. In the United States, where aromatherapy is often misunderstood as solely a cosmetic treatment, the mainstream medical community has been slower to accept it.

Paula Anne Ford-Martin

Arrhythmias

Definition

An arrhythmia is an abnormality in the heart's rhythm, or heartbeat pattern. The heartbeat can be too slow, too fast, have extra beats, skip a beat, or otherwise beat irregularly.

Description

Arrhythmias are deviations from the normal cadence of the heartbeat, which cause the heart to pump improperly. The normal heartbeat starts in the right atrium, where the heart's natural pacemaker (the sinus node) sends an electrical signal to the center of the heart to the atrioventricular node. The atrioventricular node then sends signals into the main pumping chamber to make the ventricle contract. Arrhythmias occur when the heartbeat starts in a part of the heart other than the sinus node, an abnormal rate or rhythm develops in the sinus node, or a heart conduction "block" prevents the electrical signal from traveling down the normal pathway.

More than four million Americans have arrhythmias, most of which are harmless. Middle-aged adults commonly experience arrhythmias. As people age, the probability of experiencing an arrhythmia increases. Arrhythmias often occur in people who do not have **heart disease**. In people with heart disease, it is usually the heart disease which is dangerous, not the arrhythmia. Arrhythmias often occur during and after heart attacks. Some types of arrhythmias, such as **ventricular tachycardia**, are serious and even life threatening. In the United States, arrhythmias are the primary cause of **sudden cardiac death**, accounting for more than 350,000 deaths each year.

Slow heart rates (less than 60 beats per minute) are called bradycardias, whereas fast heart rates (more than 100 beats per minute) are called tachycardias. Bradycardia can result in poor circulation of blood, and, hence, a lack of oxygen throughout the body, especially the brain. Tachycardias also can compromise the heart's ability to pump effectively because the ventricles do not have enough time to completely fill.

Arrhythmias are characterized by their site of origin: the atria or the ventricles. Supraventricular arrhythmias occur in the upper areas of the heart and are less serious than ventricular arrhythmias. **Ventricular fibrillation** is the most serious arrhythmia and is fatal unless medical help is immediate.

KEY TERMS

Bradycardia—A slow heart rate. Bradycardia is one of the two types of arrhythmia.

Electrocardiogram—A test which uses electric sensors placed on the body to monitor the heartbeat.

Electrophysiology study—A test using cardiac catheterization to stimulate an electrical current to provoke an arrhythmia. The test identifies the origin of arrhythmias and is used to test the effectiveness of antiarrhythmic drugs.

Tachycardia—A fast heart rate. Tachycardia is one of the two types of arrhythmia.

Causes and symptoms

In many cases, the cause of an arrhythmia is unknown. Known causes of arrhythmias include heart disease, **stress**, **caffeine**, tobacco, alcohol, diet pills, and **decongestants** in **cough** and cold medicines.

Symptoms of an arrhythmia include a fast heartbeat, pounding or fluttering chest sensations, skipping a heartbeat, "flip-flops," **dizziness**, faintness, **shortness of breath**, and chest pains.

Diagnosis

Examination with a stethoscope, electrocardiograms, and electrophysiologic studies is used to diagnose arrhythmias. Sometimes arrhythmias can be identified by listening to the patient's heart through a stethoscope, but, since arrhythmias are not always present, they may not occur during the physical exam.

An electrocardiogram (ECG) shows the heart's activity and may reveal a lack of oxygen from poor circulation (ischemia). Electrodes covered with conducting jelly are placed on the patient's chest, arms, and legs. They send impulses of the heart's activity through an electrical activity monitor (oscilloscope) to a recorder that traces them on paper. The test takes about 10 minutes and is performed in a physician's office. Another type of ECG, commonly known as the **exercisestress test**, measures how the heart and blood vessels respond to exertion while the patient is exercising on a treadmill or a stationary bike. This test is performed in a physician's office or an exercise laboratory and takes 15–30 minutes. Other types of ECGs include 24-hour ECG monitoring and transtelephonic monitoring. In 24-hour ECG (Holter) monitoring, the patient wears a small, portable tape

WWW.BOOKBAZ.IR

recorder connected to disks on his/her chest that record the heart's rhythm during daily activities. Transtelephonic monitoring can identify arrhythmias that occur infrequently. Similar to **Holter monitoring**, transtelephonic monitoring can continue for days or weeks, and it enables patients to send the ECG via telephone to a monitoring station when an arrhythmia is felt, or the patient can store the information in the recorder and transmit it later.

Electrophysiologic studies are invasive procedures performed in a hospital to identify the origin of serious arrhythmias and responses to various treatments. They involve **cardiac catheterization**, in which catheters tipped with electrodes are passed from a vein in the arm or leg through the blood vessels into the heart. The electrodes record impulses in the heart, highlighting where the arrhythmia starts. During the procedure, physicians can test the effects of various drugs by provoking an arrhythmia through the electrodes and trying different drugs. The procedure takes one to three hours, during which the patient is awake but mildly sedated. Local anesthetic is injected at the catheter insertion sites.

Treatment

Many arrhythmias do not require any treatment. For serious arrhythmias, treating the underlying heart disease sometimes controls the arrhythmia. In some cases, the arrhythmia itself is treated with drugs, electrical shock (**cardioversion**), automatic implantable defibrillators, artificial **pacemakers**, **catheter ablation**, or surgery. Supraventricular arrhythmias often can be treated with drug therapy. Ventricular arrhythmias are more complex to treat.

Drug therapy can manage many arrhythmias, but finding the right drug and dose requires care and can take some time. Common drugs for suppressing arrhythmias include **beta blockers**, **calcium channel blockers**, quinidine, digitalis preparations, and procainamide. Because of their potential serious side effects, stronger, desensitizing drugs are used only to treat life-threatening arrhythmias. All of the drugs used to treat arrhythmias have possible side effects, ranging from mild complications with beta blockers and **calcium** channel blockers to more serious effects of desensitizing drugs that can, paradoxically, cause arrhythmias or make them worse. Response to drugs is usually measured by ECG, Holter monitor, or electrophysiologic study.

In emergency situations, cardioversion or **defibrillation** (the application of an electrical shock to the chest wall) is used. Cardioversion restores the heart to its normal rhythm. It is followed by drug therapy to prevent recurrence of the arrhythmia.

Artificial pacemakers that send electrical signals to make the heart beat properly can be implanted under the skin during a simple operation. Leads from the pacemaker are anchored to the right side of the heart. Pacemakers are used to correct bradycardia and are sometimes used after surgical or catheter ablation.

Automatic implantable defibrillators correct life-threatening ventricular arrhythmias by recognizing them and then restoring a normal heart rhythm by pacing the heart or giving it an electric shock. They are implanted within the chest wall without major surgery and store information for future evaluation by physicians. Automatic implantable defibrillators have proven to be more effective in saving lives than drugs alone. They often are used in conjunction with drug therapy.

Ablation, a procedure to alter or remove the heart tissue causing the arrhythmia in order to prevent a recurrence, can be performed through a catheter or surgery. Supraventricular tachycardia can be treated successfully with ablation. Catheter ablation is performed in a catheterization laboratory with the patient under **sedation**. A catheter equipped with a device that maps the heart's electrical pathways is inserted into a vein and is threaded into the heart. High-frequency radio waves are then used to remove the pathway(s) causing the arrhythmia. Surgical ablation is similar in principle but it is performed in a hospital, using a cold probe instead of radio waves to destroy tissue. Ablation treatments are used when medications fail.

Maze surgery treats **atrial fibrillation** by making multiple incisions through the atrium to allow electrical impulses to move effectively. This is often recommended for patients who have not responded to drugs or cardioversion.

Alternatives

Since some arrhythmias can be life threatening, a conventional medical doctor should always be consulted first. **Acupuncture** can correct an insignificant number (1.5%) of atrial fibrillation cases. For new, minor arrhythmias, acupuncture may be effective in up to 70% of cases, but this figure may not differ much from placebo therapy. Both western and Chinese herbal remedies are also used in the treatment of arrhythmias. Since hawthorn (*Crataegus laevigata*)

dilates the blood vessels and stimulates the heart muscle, it may help to stabilize arrhythmias. It is gentle and appropriate for home use, unlike foxglove (*Digitalis purpurea*), an herb whose action on the heart is too potent for use without supervision by a qualified practitioner. Homeopathic practitioners may prescribe remedies such as *Lachesis* and aconite or monkshood (*Aconitum napellus*) to treat mild arrhythmias.

Prognosis

Advances in diagnostic techniques, new drugs, and medical technology have extended the lives of many patients with serious arrhythmias. Diagnostic techniques enable physicians to accurately identify arrhythmias, while new drugs, advances in pacemaker technology, the development of implantable defibrillators, and progress in ablative techniques offer effective treatments for many types of arrhythmia.

Prevention

Some arrhythmias can be prevented by managing stress, controlling **anxiety**, and avoiding caffeine, alcohol, decongestants, cocaine, and cigarettes.

Art therapy

Definition

Art therapy, sometimes called creative arts therapy or expressive arts therapy, encourages people to express and understand emotions through artistic expression and through the creative process.

Purpose

Art therapy provides the client-artist with critical insight into emotions, thoughts, and feelings. Key benefits of the art therapy process include:

- Self-discovery. At its most successful, art therapy triggers an emotional catharsis.
- Personal fulfillment. The creation of a tangible reward can build confidence and nurture feelings of self-worth. Personal fulfillment comes from both the creative and the analytical components of the artistic process.
- Empowerment. Art therapy can help people visually express emotions and fears that they cannot express through conventional means, and can give them some sense of control over these feelings.
- Relaxation and stress relief. Chronic stress can be harmful to both mind and body. Stress can weaken and damage the immune system, can cause insomnia and depression, and can trigger circulatory problems (like high blood pressure and irregular heartbeats). When used alone or in combination with other relaxation techniques such as guided imagery, art therapy can effectively relieve stress.
- Symptom relief and physical rehabilitation. Art therapy can also help patients cope with pain. This therapy can promote physiological healing when patients identify and work through anger, resentment, and other emotional stressors. It is often prescribed to accompany pain control therapy for chronically and terminally ill patients.

A cancer patient applies papier-mâché to an intravenous drip stand during an art therapy session. *(Ronen Zvulun/Reuters/Landov.)*

WWW.BOOKBAZ.IR

KEY TERMS

Catharsis—Therapeutic discharge of emotional tension by recalling past events.

Mandala—A design, usually circular, that appears in religion and art. In Buddhism and Hinduism, the mandala has ritual purposes and serves as a yantra (a geometric emblem or instrument of contemplation).

Organic illness—A physically, biologically based illness.

Description

Origins

Humans have expressed themselves with symbols throughout history. Masks, ritual pottery, costumes, other objects used in rituals, cave drawings, Egyptian hieroglyphics, and Celtic art and symbols are all visual records of self-expression and communication through art. Art has also been associated spiritual power, and artistic forms such as the Hindu and Buddhist mandala and Native American sand painting are considered powerful healing tools.

In the late nineteenth century, French psychiatrists Ambrose Tardieu and Paul-Max Simon published studies on the similar characteristics of and symbolism in the artwork of the mentally ill. Tardieu and Simon viewed art therapy as an effective diagnostic tool to identify specific types of mental illness or traumatic events. Later, psychologists would use this diagnostic aspect to develop psychological drawing tests (the Draw-A-Man test, the Draw-A-Person Questionnaire [DAP.Q]) and projective personality tests involving visual symbol recognition (e.g., the Rorschach Inkblot Test, the **Thematic Apperception Test** [TAT], and the Holtzman Inkblot Test [HIT]).

The growing popularity of milieu therapies at psychiatric institutions in the twentieth century was an important factor in the development of art therapy in the United States. Milieu therapies (or environmental therapy) focus on putting the patient in a controlled therapeutic social setting that provides the patient with opportunities to gain self-confidence and interact with peers in a positive way. Activities that encourage self-discovery and empowerment such as art, music, dance, and writing are important components of this approach.

Educator and therapist Margaret Naumburg was a follower of both Freud and Jung, and incorporated art into **psychotherapy** as a means for her patients to visualize and recognize the unconscious. She founded the Walden School in 1915, where she used students' artworks in psychological counseling. She published extensively on the subject and taught seminars on the technique at New York University in the 1950s. She is considered the founder of art therapy in the United States.

In the 1930s, Karl, William, and Charles Menninger introduced an art therapy program at their Kansas-based psychiatric hospital, the Menninger Clinic. The Menninger Clinic employed a number of artists in residence in the following years, and the facility was also considered a leader in the art therapy movement through the 1950s and 60s. Other noted art therapy pioneers who emerged in the 50s and 60s include Edith Kramer, Hanna Yaxa Kwiatkowska (National Institute of Mental Health), and Janie Rhyne.

Art therapy, sometimes called expressive art or art psychology, encourages self-discovery and emotional growth. It is a two-part process, involving both the creation of art and the discovery of its meaning. Rooted in Freud and Jung's theories of the subconscious and unconscious, art therapy is based on the assumption that visual symbols and images are the most accessible and natural form of communication to the human experience. Patients are encouraged to visualize, and then create, the thoughts and emotions that they cannot talk about. The resulting artwork is then reviewed and its meaning interpreted by the patient.

The "analysis" of the artwork produced in art therapy typically allows patients to gain some level of insight into their feelings and lets them to work through these issues in a constructive manner. Art therapy is practiced with individual, group, or family psychotherapy (talk therapy). While a therapist may provide critical guidance for these activities, a key feature of effective art therapy is that the patient/artist, not the therapist, directs the interpretation of the artwork.

Art therapy can be a particularly useful treatment tool for children, who frequently have limited language skills. By drawing or using other visual means to express troublesome feelings, younger patients can begin to address these issues, even if they cannot

identify or label these emotions with words. Art therapy is also valuable for adolescents and adults who are unable or unwilling to talk about thoughts and feelings.

Beyond its use in mental health treatment, art therapy is also used with traditional medicine to treat organic diseases and conditions. The connection between mental and physical health is well documented, and art therapy can promote healing by relieving **stress** and allowing the patient to develop coping skills.

Art therapy has traditionally centered on visual mediums, like paintings, sculptures, and drawings. Some mental healthcare providers have now broadened the definition to include music, film, dance, writing, and other types of artistic expression.

Art therapy is often one part of a psychiatric inpatient or outpatient treatment program, and can take place in individual or **group therapy** sessions. Group art therapy sessions often take place in hospital, clinic, shelter, and community program settings. These group therapy sessions can have the added benefits of positive social interaction, empathy, and support from peers. The client-artist can learn that others have similar concerns and issues.

Preparations

Before starting art therapy, the therapist may have an introductory session with the client-artist to discuss art therapy techniques and give the client the opportunity to ask questions about the process. The client-artist's comfort with the artistic process is critical to successful art therapy.

The therapist ensures that appropriate materials and space are available for the client-artist, as well as an adequate amount of time for the session. If the individual artist is exploring art as therapy without the guidance of a trained therapist, adequate materials, space, and time are still important factors in a successful creative experience.

The supplies used in art therapy are limited only by the artist's (and/or therapist's) imagination. Some of the materials often used include paper, canvas, poster board, assorted paints, inks, markers, pencils, charcoals, chalks, fabrics, string, adhesives, clay, wood, glazes, wire, bendable metals, and natural items (like shells, leaves, etc.). Providing artists with a variety of materials in assorted colors and textures can enhance their interest in the process and may result in a richer, more diverse exploration of their emotions in the resulting artwork. Appropriate tools such as scissors, brushes, erasers, easels, supply trays, glue guns, smocks or aprons, and cleaning materials are also essential.

An appropriate workspace should be available for the creation of art. Ideally, this should be a bright, quiet, comfortable place, with large tables, counters, or other suitable surfaces. The space can be as simple as a kitchen or office table, or as fancy as a specialized artist's studio.

The artist should have adequate time to become comfortable with and explore the creative process. This is especially true for people who do not consider themselves "artists" and may be uncomfortable with the concept. If performed in a therapy group or one-on-one session, the art therapist should be available to answer general questions about materials and/or the creative process. However, the therapist should be careful not to influence the creation or interpretation of the work.

Precautions

Art materials and techniques should match the age and ability of the client. People with impairments, such as **traumatic brain injury** or an organic neurological condition, may have difficulties with the self-discovery portion of the art therapy process depending on their level of functioning. However, they may still benefit from art therapy through the sensory stimulation it provides and the pleasure they get from artistic creation.

While art is accessible to all (with or without a therapist to guide the process), it may be difficult to tap the full potential of the interpretive part of art therapy without a therapist to guide the process. When art therapy is chosen as a therapeutic tool to cope with a physical condition, it should be treated as a supplemental therapy and not as a substitute for conventional medical treatments.

Research and general acceptance

A wide body of literature supports the use of art therapy in a mental health capacity. And as the mind-body connection between psychological well-being and physical health is further documented by studies in the field, art therapy gains greater acceptance by mainstream medicine as a therapeutic technique for organic illness.

Arterial blood gas analysis *see* **Blood gas analysis**

Arterial embolism

Definition

An embolus is a blood clot, bit of tissue or tumor, gas bubble, or other foreign body that circulates in the blood stream until it becomes stuck in a blood vessel.

Description

When a blood clot develops in an artery and remains in place, it is called a thrombosis. If all or part of the blockage breaks away and lodges in another part of the artery, it is called an **embolism**. Blockage of an artery in this manner can be the result of a blood clot, fat cells, or an air bubble.

When an embolus blocks the flow of blood in an artery, the tissues beyond the plug are deprived of normal blood flow and oxygen. This can cause severe damage and even death of the tissues involved.

Emboli can affect any part of the body. The most common sites are the legs and feet. When the brain is affected, it is called a **stroke**. When the heart is involved, it is called a **heart attack** or myocardial infarction (MI).

Causes and symptoms

A common cause of embolus is when an artery whose lining has become thickened or damaged, usually with age, allows **cholesterol** to build up more easily than normal on the artery wall. If some of the cholesterol breaks off, it forms an embolus. Emboli also commonly form from **blood clots** in a heart that has been damaged from heart attack or when the heart contracts abnormally from **atrial fibrillation**.

Other known causes are fat cells that enter the blood after a major bone fracture, infected blood cells, cancer cells that enter the blood stream, and small gas bubbles.

KEY TERMS

Atrial fibrillation—An arrhythmia; chaotic quivering of the arteries.

Thrombosis—A blockage in a blood vessel that builds and remains in one place.

Symptoms of an embolus can begin suddenly or build slowly over time, depending on the amount of blocked blood flow.

If the embolus is in an arm or leg, there will be muscle **pain**, numbness or tingling, pale skin color, lower temperature in the limb, and weakness or loss of muscle function. If it occurs in an internal organ, there is usually pain and/or loss of the organ's function.

Diagnosis

The following tests can be used to confirm the presence of an arterial embolism:

- Electrocardiogram, also known as an EKG or ECG. For this test, patches that detect electrical impulses from the heart are attached to the chest and extremities. The information is displayed on a monitor screen or a paper tape in the form of waves. Reduced blood and oxygen supply to the heart shows as a change in the shape of the waves.
- Noninvasive vascular tests. These involve measuring blood pressure in various parts of the body and comparing the results from each location. When there is a decrease in blood pressure beyond what is normal between two points, a blockage is presumed to be present.
- Angiography. In this procedure, a colored liquid material (a dye, or contrast material) that can be seen with x rays is injected into the blood stream through a small tube called a catheter. As the dye fills the arteries, they are easily seen on x-ray motion pictures. If there is a blockage in the artery, it shows up as a sudden cut off in the movement of contrast material. Angiography is an expensive procedure and does carry some risk. The catheter may cause a blood clot to form, blocking blood flow. There is also the risk of poking the catheter through the artery or heart muscle. Some people may be allergic to the dye. The risk of any of these injuries occurring is small.

Treatment

Arterial embolism can be treated with medication or surgery, depending on the extent and location of the blockage.

Medication to dissolve the clot is usually given through a catheter directly into the affected artery. If the embolus was caused by a blood clot, medications that thin the blood will help reduce the risk of another embolism.

A surgeon can remove an embolus by making an incision in the artery above the blockage and, using a catheter inserted past the embolus, drag it out through the incision.

If the condition is severe, a surgeon may elect to bypass the blocked vessel by grafting a new vessel in its place.

Prognosis

An arterial embolism is serious and should be treated promptly to avoid permanent damage to the affected area. The outcome of any treatment depends on the location and seriousness of the embolism. New arterial emboli can form even after successful treatment of the first event.

Prevention

Prevention may include diet changes to reduce cholesterol levels, medications to thin the blood, and practicing an active, healthy lifestyle.

Arteriography *see* **Angiography**
Arteriosclerosis *see* **Atherosclerosis**

Arteriovenous fistula

Definition

An arteriovenous **fistula** (AV fistula) is an abnormal connection between a vein and an artery. The connection can be congenital (present at birth). Occasionally the connection can develop because of **trauma** such as a knife or bullet wound. Most often, the AV fistula is created surgically to allow access to the vascular system for hemodialysis. When created surgically, the connection of a vein and an artery is usually done in the forearm. The fistula develops over a period of months after the surgery.

Purpose

Hemodialysis is the process of mechanically cleansing the blood when the kidneys have failed. The surgical creation of an AV fistula provides a long-lasting site through which blood can be removed and returned during hemodialysis. The fistula, which allows the person to be connected to a dialysis machine, must be prepared by a surgeon weeks or months before dialysis is started. When the vein and artery are joined, blood flow increases and the vein gradually becomes larger and stronger, creating a site that provides vascular access years longer than other types of access and with fewer complications. AV fistulas are for people who will need dialysis for long periods—either until a kidney becomes available for transplantation or for the rest of their life. Short-term access to the vascular system for dialysis can be had by the insertion of a venous catheter.

Demographics

According to the National Kidney Foundation, at the end of 2008, 485,000 people were being treated for kidney failure or end-stage renal (kidney) disease. They are of varying ages and backgrounds and typically suffer from another condition or disease that has led to kidney shutdown, and most (about 341,000 annually) will require dialysis. Among dialysis patients, over half will have an AV fistula as vascular access. In the United States, kidney failure is disproportionately high among minority populations with the highest rate being found among African Americans, Hispanic Americans, and Native Americans.

Description

The kidneys are paired organs in the mid-abdomen, one on each side of the lower back. Their function is to clean the blood of wastes and to regulate fluid and electrolyte balance in the body. Dialysis performs these functions in place of the failing kidneys. Dialysis cannot restore kidney function, but it can prolong life, often for years, by preventing the build-up of waste products in the body.

Acute kidney failure usually happens in circumstances where an extra burden is placed on the renal system. For example, acute kidney failure can occur in advanced **liver disease**, rapidly progressing terminal illnesses such as cancer and certain severe **anemias**, after severe allergic reactions, as a reaction to drugs or poisons, in heart and lung diseases, during

WWW.BOOKBAZ.IR

KEY TERMS

Access—The point where a needle or catheter is inserted for dialysis.

Acute renal (kidney) failure—Abrupt loss of kidney function, possibly temporary.

Artery—Blood vessel that carries blood away from the heart to the body.

Chronic renal (kidney) failure—Progressive loss of kidney function over several years that can result in permanent kidney failure requiring dialysis.

Electrolyte—Ions in the body that participate in metabolic reactions. The major human electrolytes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), phosphate (HPO_4^{2-}), bicarbonate (HCO_3^-), and sulfate (SO_4^{2-}).

Hypertension—High blood pressure.

the formation of **blood clots** (**embolism**), and following heart bypass surgery. Diabetes and vascular diseases, especially those with **hypertension**, are the two most common underlying diseases contributing to **chronic kidney failure**.

Many advances in the treatment of kidney failure have been made since the first attempts at dialysis treatments in the 1920s. At one time, dialysis was thought of only as a way to keep people alive until kidney function could be restored. Often the treatment for kidney failure had to be discontinued within several days because patients' veins could not endure the trauma that occurred with frequent withdrawing and replacing of blood. The first breakthrough came in 1960 with the introduction of an implantable Teflon tube, called a shunt, that became the first effective vascular access device. Since then, the development of the AV fistula has marked another important advance, allowing effective treatment for longer periods.

Hemodialysis

Dialysis is performed as critical **life support** when a person experiences acute or chronic kidney failure. It is a mechanical way to cleanse the blood and balance body fluids when the kidneys are not able to perform these essential functions. Kidney failure can, in some cases, be reversed, and dialysis can provide temporary support until renal function is restored. Dialysis may also be used in irreversible or chronic kidney shutdown when transplantation is the medical goal and the patient is waiting for a donated kidney. Some critically ill patients with life-threatening illnesses such as cancer or severe **heart disease** are not candidates for transplantation and dialysis for them is the only option for treating permanent kidney failure, also called end-stage renal disease (ESRD).

There are two types of dialysis, hemodialysis and peritoneal dialysis. In hemodialysis, the blood circulates through a machine outside the body and is filtered as it circulates. In peritoneal dialysis, the blood is filtered through a membrane that has been placed in the abdomen. Blood remains in the body and waste material is filtered into an exchange fluid through an opening in the abdomen called a port. Only hemodialysis requires an AV fistula or other vascular access.

Hemodialysis circulates blood through a dialysis machine that contains a filter membrane. The blood is slowly pumped out of the body and into the machine for cleansing. After being filtered, the blood is returned to the body through the same vascular access. About one cup (235 mL) of blood is outside the body at any given moment during the continuous circulation process.

Hemodialysis is usually done three times a week, taking between three and five hours each time. Healthcare professionals perform the procedure either at independent dialysis centers or in hospitals or medical centers. Dialysis patients must go to the hemodialysis center where they will sit to receive the treatment. Although they cannot walk around, they can watch television, read, or talk to other patients. Dialysis centers offer patient education, including videos and brochures that describe treatment options and self-care. Patients can also receive advice and information about paying for this ongoing treatment through nationally sponsored programs that are available especially for those who need long-term dialysis. Often the dialysis center offers emotional support as well, letting people meet and talk with others who have kidney problems. Some people prefer to perform their own dialysis by having a home dialysis machine. This requires that the dialysis patient and another person, usually a family member, take a three- to six-week training program to learn how to do the treatment.

Vascular access

An access or entry to the vascular system is needed to perform the blood-cleansing role of the kidneys through hemodialysis. There are three types of vascular access: AV fistula, grafts, and catheters.

ARTERIOVENOUS FISTULA. An AV fistula has proven to be the best kind of vascular access for people

whose veins are large enough, not only because it lasts longer, but also because it is less likely than other types of access to form clots or become infected. If the veins are not large enough or there is no time to wait for a fistula to develop, a graft or a catheter must be used.

GRAFT. Grafts are often the access of choice when a hemodialysis patient has small veins that will not likely develop properly into a fistula. This type of access uses a synthetic tube implanted under the skin of the arm that can be used repeatedly for needle placement. Unlike a fistula, which requires time to develop, a graft can be used as soon as two to three weeks after placement. Grafts are known to have more problems than fistulas, such as clots and infection, and will likely need replacement sooner.

CATHETER. A catheter is used to provide temporary vascular access. When **kidney disease** has progressed quickly, there may not be time to prepare a permanent vascular access site before dialysis treatments are started. The catheter is a tube that is inserted into a vein in the neck, chest, or in the leg near the groin. Two chambers in the tube allow blood to flow in and out. Once the catheter is in place, needle insertion is not necessary. Catheters are effective for dialysis for several weeks or months while surgery is performed and an AV fistula develops. They are not selected for permanent access because they can clog, become infected, or cause the veins to narrow. Long-term catheter access must be used in patients for whom AV fistula or graft surgery has not been successful. If more than three weeks' use is expected, catheters can be made to tunnel under the skin, which increases comfort and reduces complications

Diagnosis/Preparation

Diagnosis

The diagnosis of kidney disease and its progression to kidney failure is typically made by a nephrologist, a specialist in kidney structure and function. The nephrologist will determine whether the patient has acute or chronic kidney failure and if dialysis is appropriate for the patient. If dialysis is recommended, the nephrologist will determine if an AV fistula is the ideal vascular access for the patient. To make these determinations, the nephrologist will need to evaluate the patient's general health, especially the presence of any underlying disease. Kidney function must be evaluated and determined to be seriously impaired before dialysis is recommended. It is typically started when kidney function is down to about 10% of its normal level. Among other tests that will be performed, such as **urinalysis** with microscopic examination of the urine, several blood and urine tests can be used to measure a person's kidney function when chronic or acute kidney failure is suspected. Some of the tests measure electrolytes and other metabolites produced by the body that are normally excreted by the kidneys and passed through urine. The tests can measure effectively if the kidney is filtering out these materials, and how much remains in the blood. These tests include, but are not limited to the following:

- serum creatinine—found in higher levels in the blood if kidneys fail;
- urinary creatinine—readings are lower in kidney failure;
- urinary output—measuring both fluid intake and all urine produced;
- urinary osmolality—measures the concentration of the urine, an indicator of kidney filtering ability;
- blood urea nitrogen (BUN)—harmful nitrogen waste increases in the blood as kidney function decreases; and
- electrolytes in blood and urine—ions in the blood such as sodium, potassium, magnesium, and chloride are often out of balance when kidneys fail. Potassium, for example, increases in the blood during kidney failure and can cause heart irregularities.

Description

Surgery to create an AV fistula is usually done using a local anesthetic that is injected into the forearm at the site of the proposed fistula. The procedure is performed in a hospital or at an outpatient surgery if the patient is not already hospitalized and has no serious underlying disease.

After cleaning and sterilizing the site, the surgeon makes a small incision in the forearm sufficient to allow the permanent uniting of a vein and an artery. The blood vessels will be appropriately blocked to stop blood flow while incisions are made to join them. Silk sutures, just as those used in other types of surgical incisions, are used to close incised areas as needed after the vein and artery have been joined. Once joined, blood flow increases. The vein will become thicker, and over a period of months the connection will become strong and develop into the fistula that will allow permanent vascular access.

Aftercare

The hemodialysis patient should expect needle insertion in the AV fistula at every dialysis session. Patients who prefer to insert their own needles or who perform dialysis at home will need training, and all

WWW.BOOKBAZ.IR

patients have to learn how to avoid infection and to protect the vascular access. Because vascular access problems can lead to treatment failure, the AV fistula requires regular care to make dialysis easier and to help avoid clots, infection, and other complications.

Patients can help protect the access by taking the following steps:

- making sure the access is checked before each treatment
- not allowing blood pressure to be taken on the access arm
- checking the pulse in the access every day
- keeping the access clean at all times
- using the access site only for dialysis
- taking care not to bump or cut the access
- avoiding wearing tight jewelry or clothing near or over the access site
- avoiding lifting heavy objects or putting pressure on the access arm
- sleeping with the access arm free, not under the head or body

Risks

The most frequent complications in hemodialysis relate to the vascular access site where needles are inserted. Complications include infection around the access area and formation of clots in the fistula. Usually, because they are in the fistula itself, these clots are not life threatening. The greatest danger is that clots may block the fistula and have to be removed surgically. Frequent clotting may require creating a back-up fistula at another site, to allow dialysis when one access is blocked.

Other complications from dialysis are not directly related to the vascular access. For example, when the kidneys have shut down, they produce very little urine. Because dialysis is the only way people with kidney failure can balance fluid levels in their bodies, hemodialysis can cause bloating and fluid overload, indicating that too much fluid remains in the body. If fluid overload occurs, patients develop swollen ankles, puffy eyes, weight gain, and **shortness of breath**. Fluid overload can cause heart and circulatory problems and fluctuations in blood pressure. Medications may be prescribed and changes in fluid intake or diet may be made to help balance fluids safely in conjunction with dialysis.

Other problems that can occur during or after hemodialysis include:

- low blood pressure when fluid and wastes are removed from the blood too quickly
- nausea due to changes in blood pressure
- muscle cramps from the removal of too much fluid from the blood
- headaches near the end of a dialysis session resulting from changes in the concentration of fluid and waste in the blood
- fatigue after treatment, lasting sometimes into the next day

Results

An AV fistula can usually be created and can function well with no adverse affects in a person whose veins are large enough. The amount of time it takes to develop the fistula after surgery (usually months) depends upon the size and strength of the patient's blood vessels and on the person's health and nutritional status. When the fistula develops, the thickened vein that has been joined to an artery can be seen in the arm and a pulse can be felt in it. The early development of an AV fistula as access for long-term dialysis has been shown to improve the survival of patients with chronic renal failure and to reduce the chances of being hospitalized with complications. It also gives patients a better opportunity to choose self-dialysis as their treatment.

With good **nutrition** and a fully functioning AV fistula, dialysis patients can be relatively comfortable and free of complications. People may become tired and uncomfortable when it is close to the time for their next dialysis session. This is to be expected because wastes are building up in the blood, and the body senses that it is time to remove them.

Morbidity and mortality rates

Earlier use of dialysis, especially with AV fistula access, has been shown to increase survival in patients with renal failure. The AV fistula is designed to improve the effectiveness of dialysis and is reported to present fewer risks and complications, reduced incidence of clotting and infection, and longer use than other types of vascular access.

Kidney failure is reported to account for 1% of hospital admissions in the United States. It occurs in 2–5% of patients hospitalized for other conditions, surgeries, or diseases. In patients undergoing cardiac bypass surgery, 15% are reported to require dialysis for kidney failure. Overall, deaths in people undergoing dialysis are reported to be about 50% because of the multi-organ dysfunction that has influenced kidney failure.

Arteriovenous malformations. *(Custom Medical Stock Photo, Inc.)*

Arteriovenous malformations

Definition

Arteriovenous malformations are blood vessel defects that occur before birth when the fetus is growing in the uterus (prenatal development). The blood vessels appear as a tangled mass of arteries and veins. They do not possess the capillary (very fine blood vessels) bed which normally exists in the common area where the arteries and veins lie in close proximity (artery-vein interface). An arteriovenous malformation (AVM) may hemorrhage, or bleed, leading to serious complications that can be life-threatening.

Description

AVMs represent an abnormal interface between arteries and veins. Normally, arteries carry oxygenated blood to the body's tissues through progressively smaller blood vessels. The smallest are capillaries, which form a web of blood vessels (the capillary bed) through the body's tissues. The arterial blood moves through tissues by these tiny pathways, exchanging its load of oxygen and nutrients for carbon dioxide and other waste products produced by the body cells (cellular wastes). The blood is carried away by progressively larger blood vessels, the veins. AVMs lack a capillary bed and arterial blood is moved (shunted) directly from the arteries into the veins.

AVMs can occur anywhere in the body and have been found in the arms, hands, legs, feet, lungs, heart, liver, and kidneys. However, 50% of these malformations are located in the brain, brainstem, and spinal cord. Owing to the possibility of hemorrhaging, such AVMs carry the risk of **stroke**, **paralysis**, and the loss of speech, memory, or vision. An AVM that hemorrhages can be fatal.

Approximately three of every 100,000 people have a cerebral AVM and roughly 40-80% of them will experience some bleeding from the abnormal blood vessels at some point. The annual risk of an AVM bleeding is estimated at about 1-4%. After age 55, the risk of bleeding decreases. Pre-existing high blood pressure or intense physical activity do not seem to be associated with AVM hemorrhage, but **pregnancy** and labor could cause a rupture or breaking open of a blood vessel. An AVM hemorrhage is not as dangerous as an aneurysmal rupture. (An aneurysm is a swollen, blood filled vessel where the pressure of the blood causes the wall to bulge outward.) There is an approximate 10% fatality rate associated with AVM hemorrhage, compared to a 50% fatality rate for ruptured aneurysms.

Although AVMs are congenital defects, meaning a person is born with them, they are rarely discovered before age 20. A genetic link has been proposed for some AVMs, but studies are only suggestive, not

WWW.BOOKBAZ.IR

KEY TERMS

Aneurysm—A weak point in a blood vessel where the pressure of the blood causes the vessel wall to bulge.

Angiography—A mapping of the brain's blood vessels, using x-ray imaging.

Capillary bed—A dense network of tiny blood vessels that enables blood to fill a tissue or organ.

Hydrocephalus—Swelling of the brain caused by an accumulation of fluid.

Lumbar puncture—A diagnostic procedure in which a needle is inserted into the lower spine to withdraw a small amount of cerebrospinal fluid. This fluid is examined to assess trauma to the brain.

Saccular aneurysm—A type of aneurysm that resembles a small sack of blood attached to the outer surface of a blood vessel by a thin neck.

positive. The majority of AVMs are discovered in people age 20–40. Medical researchers estimate that the malformations are created during days 45–60 of fetal development. A second theory suggests that AVMs are primitive structures that are left over from the period when fetal blood circulating systems began to develop.

However they form, AVMs have blood vessels that are abnormally fragile. The arteries that feed into the malformation are unusually swollen and thin walled. They lack the usual amount of smooth muscle tissue and elastin, a fibrous connective tissue. These blood vessels commonly accumulate deposits of **calcium** salts and hyalin. The venous part of the malformation receives blood directly from the artery. Without the intervening capillary bed, the veins receive blood at a higher pressure than they were designed to handle. This part of the malformation is also swollen (dilated) and thin walled. There is a measurable risk of an aneurysm forming near an AVM, increasing the threat of hemorrhage, brain damage, and death. Approximately 10–15% of AVMs are accompanied by saccular aneurysms, a type of aneurysm that looks like a small sac attached to the outer wall of the blood vessel.

Although the malformation itself lacks capillaries, there is often an abnormal proliferation of capillaries next to the defect. These blood vessels feed into the malformation, causing it to grow larger in some cases. As the AVM receives more blood through this "steal," adjacent brain tissue does not receive enough. These areas show abnormal nerve cell growth, cell death, and deposits of calcium in that area (calcification). Nerve cells within the malformation may demonstrate abnormal growth and are believed to be nonfunctional.

Causes and symptoms

Most people do not realize that they have an AVM unless it hemorrhages enough to produce symptoms. Small AVMs are more likely to hemorrhage. If a hemorrhage occurs, it produces a sudden, severe **headache**. The headache may be focused in one specific area or it may be more general. It can be mistaken for a migraine in some cases. The headache is accompanied by other symptoms, such as **vomiting**, a stiff neck, sleepiness, lethargy, confusion, irritability, or weakness anywhere in the body. Seizures occur in about a quarter of AVM cases. A person may experience decreased, double, or blurred vision. Hemorrhaging from an AVM is generally less dangerous than hemorrhaging from an aneurysm, with a survival rate of 80–90%.

Other symptoms occur less frequently, but sometimes appear alongside major symptoms such as the sudden severe headache. Additional warning signs of a bleeding AVM are impaired speech or smell, **fainting**, facial paralysis, a drooping eyelid, **dizziness**, and ringing or buzzing in the ears.

Although large AVMs are less likely to hemorrhage, they can induce symptoms based on their mass alone. Large AVMs exert pressure against brain tissue, cause abnormal development in the surrounding brain tissue, and slow down or block blood flow. **Hydrocephalus**, a swelling of brain tissue caused by accumulated fluids, may develop. The warning signs associated with a large non-bleeding AVM are similar to the symptoms of a small malformation that is bleeding. Unexplained headaches, seizures, dizziness, and neurological symptoms, such as sensory changes, are signals that demand medical attention.

Diagnosis

Based on the clinical symptoms such as severe headache and neurological problems, and after a complete neurologic exam, a computed tomography scan (CT) of the head will be done. In some cases, a whooshing sound from arteries in the neck or over the eye or jaw (called a bruit), can be heard with a stethoscope. The CT scan will reveal whether there has been bleeding in the brain and can identify AVMs larger than 1 in. (2.5 cm). **Magnetic resonance**

imaging (MRI) is also used to identify an AVM. A **lumbar puncture**, or spinal tap, may follow the MRI or CT scan. A lumbar puncture involves removing a small amount of cerebrospinal fluid from the lower part of the spine. Blood cells or blood breakdown products in the cerebrospinal fluid indicate bleeding.

To pinpoint where the blood is coming from, a cerebral **angiography** is done. This procedure uses x rays to map out the blood vessels in the brain, including the vessels that feed into the malformation. The information gained from angiography complements the MRI and helps distinguish the precise location of the AVM.

Treatment

Neurosurgeons consider several factors before deciding on a treatment option. There is some debate over whether or not to treat AVMs that have not ruptured and are not causing any symptoms. The risks and benefits of proceeding with treatment need to be measured on an individual basis, taking into account factors such as the person's age and general health, as well as the AVM's size and location. Several treatment options are available, both for symptomatic or asymptomatic AVMs. These treatment options may be used alone or in combination.

Surgery

Removing the AVM is the surest way of preventing it from causing future problems. Both small and large AVMs can be handled in surgery. Surgery is recommended for superficial AVMs, but may be too dangerous for deep or very large AVMs. Unless it is an emergency situation, an AVM that has hemorrhaged is treated conservatively for several weeks. Conservative treatment consists of managing the immediate symptoms and allowing the patient's condition to stabilize. Surgery requires general **anesthesia** and a longer period of recuperation than any other treatment option.

Radiation

Radiation is particularly useful to treat small (under 1 in.) malformations that are deep within the brain. Ionizing radiation is directed at the malformation, destroying the AVM without damaging the surrounding tissue. Radiation treatment is accomplished in a single session and it is not necessary to open the skull. However, success can only be measured over the course of the following two years. A year after the procedure, 50–75% of treated AVMs are completely blocked; two years after radiation treatment, the percentage increases to 85-95%.

Embolization

Embolization involves plugging up access to the malformation. This technique does not require opening the skull to expose the brain and can be used to treat deep AVMs. Using x-ray images as a guide, a catheter is threaded through the artery in the thigh (femoral artery) to the affected area. The patient remains awake during the procedure and medications can be administered to prevent discomfort. The blood vessel leading into the AVM is assessed for its importance to the rest of the brain before a balloon or other blocking agent is inserted via the catheter. The block chokes off the blood supply to the malformation. There may be a mild headache or nausea associated with the procedure, but patients may resume normal activities after leaving the hospital. At least two to three embolization procedures are usually necessary at intervals of two to six weeks. At least a three-day hospital stay is associated with each embolization.

Prognosis

Approximately 10% of AVM cases are fatal. Seizures and neurological changes may be permanent in another 10-30% cases of AVM rupture. If an AVM bleeds once, it is about 20% likely to bleed again in the next year. As time passes from the initial hemorrhage, the risk for further bleeding drops to about 3-4%. If the AVM has not bled, it is possible, but not guaranteed, that it never will. Untreated AVMs can grow larger over time and rarely go away by themselves. Once an AVM is removed and a person has recovered from the procedure, there should be no further symptoms associated with that malformation.

WWW.BOOKBAZ.IR

Arthrography

Definition

Arthrography is a procedure during which images of a joint are taken after injection of a contrast dye to help delineate the structures. A needle is placed into the joint space under fluoroscopy (a type of x-ray equipment that shows a live x-ray image).

Purpose

Frequently, arthrography is ordered to determine the cause of unexplained joint **pain** or functional problems. This fluoroscopic procedure can show the internal workings of specific joints and outline soft tissue structures. The procedure may also be conducted to identify problems with the ligaments, cartilage, tendons, or joint capsule of the hip, shoulder, knee, ankle, wrist, or other joints. An arthrography procedure may locate cysts in the joint area, evaluate problems with the joint's arrangement and function, indicate the need for joint replacement, or show problems with existing joint replacement (prostheses). The most commonly studied joints are the knee and shoulder.

Description

Arthrography may be referred to as "joint radiography" or "x rays of the joint." The term *arthrogram* may be used interchangeably with arthrography. The joint area will be cleaned and a local anesthetic will be injected into the tissues around the joint to anesthetize (or numb) the area. Next, if fluids are present in the joint, the physician may suction them out (aspirate) with a needle. These fluids may be sent to a laboratory for further study. **Ultrasound**, computed tomography (CT), or fluoroscopy is used to view the knee while a needle is introduced into the joint space in order to inject the contrast material. The purpose of contrast agents in x-ray procedures is to help highlight details of areas under study by making them opaque. Agents for arthrography are generally air- and water-soluble dyes, the most common containing iodine. Air and iodine may be used together or independently. After the contrast agent is administered, the site of injection will be sealed, and the patient may be asked to bend and flex the joint to distribute the contrast.

An x-ray image of the knees of a patient with cysts caused by rheumatoid arthritis. The cysts appear as dark areas just below the knee joints. *(Custom Medical Stock Photo, Inc.)*

Before the contrast medium can be absorbed by the joint itself, several films will be quickly taken under the guidance of the fluoroscope. The patient will be asked to move the joint into a series of positions, keeping still between positioning. Sometimes, the patient will experience some tingling or discomfort during the procedure, which is normal and due to the contrast. Following fluoroscopic tracking of the contrast, standard x rays of the area may also be taken. The entire procedure will last about one hour.

Generally, a joint is evaluated first by **magnetic resonance imaging** (MRI) instead of an arthrogram, or by an MRI combined with the arthrogram. Gadolinium, an MRI contrast agent, is injected if the arthrogram is performed as part of an MRI procedure. If the arthrogram is performed as part of an MRI arthrogram, the MRI scan will then be obtained immediately afterward.

Preparation

It is important to discuss any known sensitivity to local anesthetics or iodine prior to this procedure. A physician should explain the procedure and the risks associated with contrast agents and ask the patient to sign an informed consent form. If iodine contrast will be administered, the patient may be instructed not to eat or drink anything for a period of hours before the exam. The time frame of **fasting** may range from only 90 minutes prior to the exam up to the night before. There is no other preparation necessary.

Aftercare

The affected joint should be rested for approximately 12 hours following the procedure. The joint may be wrapped in an elastic bandage, and the patient should receive instructions on the care and changing of the bandage. Noises in the joint such as cracking or clicking are normal for a few days following arthrography. These noises are the result of liquid in the joints. Swelling may also occur and can be treated

KEY TERMS

Aspirate—Remove fluids by suction, often through a needle.

Contrast (agent, medium)—A substance injected into the body that outlines certain structures that would otherwise be hard to see on a radiograph (film).

Fluoroscope—A device used in some radiology procedures that provides immediate images and motion on a screen, much like those seen at airport baggage security stations.

Radiologist—A medical doctor specially trained in radiology (x ray) interpretation and its use in the diagnosis of diseases and injuries.

X ray—A form of electromagnetic radiation with shorter wavelengths than normal light. X rays can penetrate most structures.

with application of ice or cold packs. A mild pain reliever can be used to lessen pain in the first few days. However, if any of these symptoms persist for more than a few days, patients are advised to contact their physician.

Risks

In some patients, iodine can cause allergic reactions ranging from mild nausea to severe cardiovascular or nervous system complications. Since the contrast dye is put into a joint, rather than into a vein, allergic reactions are rare. Facilities licensed to perform contrast exams should meet requirements for equipment, supplies, and staff training to handle a possible severe reaction. Infection or joint damage are possible, although not frequent, complications of arthrography.

Results

A normal arthrography exam will show proper placement of the dye or contrast medium throughout the joint structures, joint space, cartilage, and ligaments.

The abnormal placement of dye may indicate **rheumatoid arthritis**, cysts, joint dislocation, tear of the rotator cuff, tears in the ligament, and other conditions. The entire lining of the joint becomes opaque from the technique, which allows the radiologist to see abnormalities in the intricate workings of the joint. In the case of recurrent shoulder **dislocations**, arthrography results can be used to evaluate damage. Patients with hip prostheses may receive arthrography to evaluate proper placement or function of their prostheses.

Arthroplasty

Definition

Arthroplasty is surgery performed to relieve **pain** and restore range of motion by realigning or reconstructing a dysfunctional joint.

Purpose

The goal of arthroplasty is to relieve pain and restore function in a severely disabled joint. This surgery is usually performed when **physical therapy** or nonsurgical medical treatment have not reduced pain or improved function of the affected joint. There are two types of arthroplastic surgery: joint resection and interpositional reconstruction.

Joint resection involves removing a portion of bone from a stiffened joint to increase space between the bones forming the joint and improve range of motion. While pain is relieved and motion is restored, the joint may be less stable. Scar tissue may also develop, eventually filling the space and narrowing the gap between the bones.

Interpositional reconstruction is surgery to reshape the joint and to add a prosthetic disk as a cushion between the bones forming the joint. The prosthesis can be made of plastic, metal, or ceramic material, or may be formed from body tissue such as skin, muscle, or fascia. When interpositional reconstruction fails, total joint replacement may be necessary. Joint replacement is referred to as total joint arthroplasty.

In the early 2000s, total joint arthroplasty became the operation of choice for most chronic knee and hip problems because of advances in the type and quality of prostheses (artificial joints). Elbow, shoulder, ankle, and finger joints are more likely to be treated with joint resection or interpositional reconstruction, although surgery on smaller joints, such as the toe, have become more common as the functionality and reliability of smaller artificial joints have improved.

Arthroplasty is performed on people experiencing severe pain and disabling joint stiffness. **Osteoarthritis** (OA), a degenerative joint disease resulting from reduced joint repair capability as people age, is a common cause of joint destruction. Symptoms include pain and impaired movement, and OA is the most common underlying condition leading to hip and **knee replacement**. Other causes include **rheumatoid arthritis** (RA), **hemophilia**, synovitis, and rare bone diseases, all of which can destroy cartilage and disable joints. Joint resection, rather than joint replacement, is more likely to be performed on people with RA, especially when the elbow joint is involved. Joint replacement is usually reserved for older patients because the life of replacement joints is limited to about 15 years. The younger the patient, the greater the reliance on nonsurgical treatment, although this is changing as the quality of replacement joints increases, especially for knee replacement.

Demographics

The most frequent replacement surgeries are knee and hip replacements, and the majority of patients who have arthroplastic surgery are men and women aged 65 years or older with osteoarthritis or **obesity**. According to a study published in *JAMA*, the number of U.S. Medicare enrollees undergoing total knee arthroplasty more than doubled in the 20 years between 1991 and 2010, increasing from 93,230 to 243,802. The rates of knee and **hip replacement** are increasing as the population ages and longevity increases. In patients aged 65–74, 75–84, and over 85, the rates increased from 5.4, 6.6, and 2.6 per 1,000 people in 2000, to 9.1, 10.2, and 4.0 in 2006, respectively. More women than men are affected among those over age 45. However, the majority of those with osteoarthritis under age 45 are men, including athletes and physical laborers who have experienced traumatic joint injury.

Arthroplasty is reserved for the most severely afflicted—approximately 3% of all patients with osteoarthritis. In addition, approximately 1% of the population worldwide has RA, which affects people of all ages. Few people with RA have arthroplastic surgery, however, because this chronic autoimmune disease is a constitutional illness that affects multiple joints (usually bilaterally) and overall health status. Treatment for RA often involves the use of immunosuppressive medications, which increases patients' risk of infection and reduces the likelihood of positive surgical results.

Description

An orthopedic surgeon performs arthroplasty, including joint resection, interpositional reconstruction, and total joint arthroplasty (joint replacement). Orthopedic surgeons are board certified in their specialty and members of the American Academy of Orthopedic Surgeons (AAOS).

Orthopedic hospitals specialize in treating orthopedic conditions and performing **orthopedic surgery**. Although some orthopedic surgeries may

be performed in other hospitals and medical centers, better surgical results have been reported in the specialized centers.

Arthroplasty may be performed under general **anesthesia** (affecting the entire body) or regional (numbing a specific large area of the body). Surgeons often prefer regional spinal or epidural anesthesia for knee or hip arthroplasty. Although joint surgery is performed in many hospitals and medical centers, orthopedic hospitals that specialize in joint surgery tend to have higher success rates and fewer complications than less specialized centers.

In joint resection, the surgeon makes an incision at the joint, then carefully removes the minimum amount of bone necessary to allow free movement of the joint. The more bone that remains, the more stable the joint. Ligament attachments are preserved as much as possible. In interpositional reconstruction, both bones of the joint are reshaped, and a disk of either plastic, metal, or ceramic material or the patient's own tissue is placed between the bones to prevent their rubbing together. The length of the hospital stay depends on the joint affected. In the absence of complications, a typical stay is brief. For total joint replacement, the entire joint is removed and replaced with an artificial joint. The hospital stay and **rehabilitation** period for total joint replacement tends to be longer than for joint resection or interpositional reconstruction.

Diagnosis

Significant disabling pain, deformity, and reduced quality of life are the primary indications for arthroscopic procedures. Patients at this stage of discomfort and disability will most likely have already been diagnosed with a form of arthritis. Pain and stiffness on weight-bearing joints are the major symptoms that patients report, and some experience night pain, as well. Other symptoms may include stiffness, swelling, and locking of the joint. The joint may even give way, particularly when the knees or hips are affected.

To determine the extent of disability, the referring physician and/or the surgeon will ask about walking distance, sporting ability, the need for walking aids, and the ability to perform self-care tasks such as dressing and bathing. Besides evaluation of the joint itself and level of mobility, the clinical examination will include evaluation of the patient's general health, the condition of the ligaments and muscles around the affected joint, and an assessment of the patient's mental outlook and social circumstances to help develop the most effective postoperative rehabilitation plan.

Diagnostic testing will typically include:

- x rays of the affected joint (and often other joints as well) to determine loss of joint space and to differentiate between OA and RA
- imaging studies, such as computed tomography (CT) scans, magnetic resonance (MRI), and bone densitometry to assess bone loss or bone infection
- cardiac tests, such as an electrocardiogram, to evaluate the heart and circulatory system
- blood tests to rule out infection and possibly to confirm arthritis

Preparation

Before arthroplastic surgery, standard preoperative blood and urine tests are performed to evaluate general health status and to rule out such conditions as anemia and infection. If a patient has a history of bleeding, the surgeon will ask that clotting tests be performed. The patient will meet with the anesthesiologist to discuss any special conditions that may affect the administration of anesthesia. Surgery will not be performed if infection is present anywhere in the body or if the patient has certain heart or lung diseases. Smokers will be asked to stop **smoking**. Weight loss may also be recommended for overweight patients. If surgery involves deep tissue and muscle, such as total hip arthroplasty, the surgeon may order units of blood to be prepared in case **transfusion** is needed to replace blood lost during the surgery. Healthy patients may be asked to donate their own blood, which will be returned to them at the time of surgery (autologous transfusion). Certain pain medications may have to be discontinued in the weeks just prior to surgery.

Aftercare

Immediately after surgery, while still in the hospital, patients will be given pain medications for the recovery period and **antibiotics** to prevent infection. When patients are discharged after joint surgery, they must be careful not to overstress or destabilize the joint. Normally, this requires rest at home for a period of days to weeks. Physical therapy will begin almost immediately to improve strength and range of motion. Physical therapy is the most important aid to recovery and may continue for several months. Activity may resume gradually, using devices such as walkers or crutches, as recommended by the physical therapist. Lifestyle changes may include the use of special seating or sleeping surfaces and employing **home care** assistance for help with shopping, cooking, and household tasks.

WWW.BOOKBAZ.IR

Risks

Joint resection and interpositional reconstruction do not always produce successful results, especially in patients with rheumatoid arthritis, a chronic inflammatory disease that may continue to narrow the joint space and accelerate the formation of scar tissue. Repeat surgery or total joint replacement may be necessary. As with any major surgery, there are always risks of an allergic reaction to anesthesia, postoperative infection, or the formation of **blood clots** (**thrombophlebitis**) that may cause pain and swelling near the surgery site and travel through the veins to other parts of the body. A joint that has undergone surgery is less stable than a healthy joint, and dislocation or loosening of the resected joint may occur, especially with inappropriate physical activity.

Results

Most patients enjoy an improved range of motion in the joint and relief from pain. Younger people may be able to return to some form of low-impact sports activity. However, people who have degenerative or inflammatory diseases must understand that they will not suddenly have a normal joint, even though they will gain pain relief and improved function.

Morbidity and mortality rates

Although infection is a rare complication in arthroplasty, affecting only 1% of patients, it is the most serious and potentially debilitating. Postoperative revision or prosthetic infection may involve repeat surgeries, a greater number of hospitalizations, and the risk of **sepsis**. The number of deaths for all arthroplasty surgeries is less than 1%, with death more likely to occur among seniors and those with other serious medical conditions.

Alternatives

Pain management alone, particularly with the availability of more effective pain medicines that have fewer side effects, is the primary nonsurgical option when the underlying diagnosis is a form of arthritis. **Nonsteroidal anti-inflammatory drugs** (NSAIDs) are commonly prescribed for patients with arthritis. Those with RA are given immunosuppressant medications to suppress irregular immune system activity, shown to be a factor in this type of arthritis. A range of **nutritional supplements** and **vitamins** are reported to offer health benefits to people with OA. Among them, the combination of glucosamine and chondroitin sulfate has been shown to offer some relief of pain and stiffness. Weight loss is sometimes recommended, since overweight status or obesity increase pressure on weight-bearing joints.

Because immobility of the affected joint can increase pain and stiffness, patients with joint disease are usually encouraged to continue some type of physical activity. Keeping the muscles strong through modest non-weight-bearing **exercise** such as stretching or swimming, is often recommended to help support the joint and maintain mobility. Various devices, such as braces or orthopedic shoes, may be recommended, as well as walking aids. Safety rails, special elevated toilet-seat extensions, and bath and shower seats can make the patient more comfortable in daily life. **Movement therapy** such as **yoga**, **Pilates**, tai chi, and dance may help maintain joint flexibility and slow chronic arthritis symptoms. **Occupational therapy**, **massage therapy**, and physiotherapy may help improve range of motion and overall comfort, as well as patient confidence.

KEY TERMS

Cartilage—The slippery tissue that covers the ends of joint bones.

Fascia—Thin connective tissue covering or separating the muscles and internal organs of the body.

Osteoarthritis—A degenerative wear-and-tear joint disease associated with diminished joint repair capability during aging.

Prosthesis—An artificial joint, part of a joint, or limb.

Rheumatoid arthritis—A chronic autoimmune disease characterized by inflammation of multiple joints and crippling pain and stiffness.

Synovial fluid—A fluid that lubricates the joints, facilitates motion, and helps prevent wearing of the bones.

Synovitis—Inflammation of the synovium, the thin membrane in the joint.

Thrombophlebitis—A condition in which blood clots (thrombi) form in veins near a surgery site, resulting in swelling and pain; clots may travel via veins to the heart, lungs or brain, causing serious complications.

Arthroscopic surgery

Definition

Arthroscopic surgery is a minimally invasive procedure that allows surgeons to visualize, diagnose, and treat problems inside joints through tiny incisions. The name is derived from the Greek words *arthron*, joint, and *skopein*, to look at. **Arthroscopy** is performed using an arthroscope, a pencil-sized fiber-optic instrument with a magnifying lens and lighting system that is passed through a small incision to enable a close look inside a joint. Attaching a tiny video camera to the arthroscope provides a clear view of the joint interior, helping to avoid making a larger surgical incision.

Purpose

Arthroscopic surgery is performed to diagnose, treat, and monitor acute or chronic joint injuries and diseases that affect the joints. Diagnostic arthroscopic surgery is performed when other assessments, such as a medical history, physical exam, x rays, or bone scans, do not provide a definitive diagnosis. Corrective arthroscopic surgery is used primarily to remove bone or cartilage or repair tendons or ligaments.

Demographics

More than 4 million knee arthroscopies are performed worldwide each year, according to the American Orthopaedic Society for Sports Medicine, along with 1.4 million arthroscopic shoulder surgery procedures. There is no significant variance for this procedure among ethnicities or age brackets. However, males and females under the age of 40 tend to be more prone to athletic-type injuries that may be diagnosed or repaired with an arthroscopic procedure. Older patients may have arthroscopic procedures done to diagnose, treat, or repair issues related to the natural **aging** process before undergoing extensive surgical procedures such as total joint placement.

Description

Arthroscopic surgery can be performed on any joint in the body but is performed most commonly on the knees and shoulders, as well as the ankles, wrists, elbows, and hips. Knee joints are large enough to allow free movement of arthroscopic instruments and are especially able to benefit from this type of examination and treatment. The technique is valued because it allows surgeons to see inside the joint through incisions as tiny as a quarter of an inch (about 1 centimeter), rather than the large incisions required in open surgery procedures. The accuracy of arthroscopy is said to be 100% for diagnosis compared to diagnostic imaging techniques such as **magnetic resonance imaging** (MRI). Arthroscopic surgery may be used to relieve mechanical joint problems such as buckling, stiffness, or locking, and can preclude or delay the need for more aggressive surgery such as joint replacement. Recovery is faster with

A. The anatomy of the knee from the front with the leg bent. B. To repair a torn meniscus, three small incisions are made into the knee to admit laparoscopic instruments. C. Fluid is injected into the joint to aid in the operation. The injury is visualized via the instruments, and the torn area is removed. *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

arthroscopic surgery since it is less invasive, and scarring is also reduced.

In arthroscopic surgery, an orthopedic surgeon applies the arthroscope, fitted with a lens, a light source, and a miniature video camera, to examine and treat structures inside a joint, including bones, cartilage, and surrounding tissue. Advanced fiber optics developed in the 1970s and '80s allow even more detail to be seen than in open surgery, often identifying problems that may have been difficult to diagnose with other methods. Highlighted images of the structures are transmitted to a television monitor in the operating room. The type and extent of the injury can be determined, and repair or correction can be performed at the same time if necessary. Some of the most common joint problems diagnosed and treated with arthroscopic surgery are:

- synovitis (inflamed joint lining) of the knee, shoulder, elbow, wrist, or ankle
- shoulder injuries, including rotator cuff tendon tears, impingement syndrome, and dislocations
- knee injuries, including meniscal (cartilage) tears, wearing down of or injury to the cartilage cushion, and anterior cruciate ligament tears with instability

KEY TERMS

Arthroscope—A pencil-sized fiber-optic instrument fitted with a lens, light source, and camera, used for detailed examination of joints.

Cartilage—The slippery tissue that covers and protects the ends of joint bones.

Meniscus (meniscal)—A fibrous, cartilaginous structure that divides a joint cavity.

Open surgery—Surgery using a large incision to lay open an area for examination or treatment; in joint surgery, the whole joint is exposed.

Osteoarthritis—A degenerative joint disease resulting from reduced joint repair capability associated with aging.

Rheumatoid arthritis—A chronic autoimmune disease characterized by inflammation of multiple joints and crippling effects.

Synovitis—Inflammation of the synovium, the thin membrane lining the joint.

- wrist injuries such as carpal tunnel syndrome
- loose bodies of bone and/or cartilage in the knee, shoulder, elbow, ankle, or wrist
- torn floating cartilage or surface cartilage
- joint damage caused by rheumatoid arthritis or osteoarthritis

Arthroscopic procedures are performed in a hospital or outpatient surgical facility by an orthopedic surgeon. The type of **anesthesia** used (local, spinal, or general) and operative time of the procedure vary depending on the joint requiring surgery, the type and extent of the suspected joint injury, and/or the complexity of the anticipated repair. Arthroscopic surgery rarely takes more than an hour. Most patients who have arthroscopic surgery, whether diagnostic or corrective, are discharged on the same day as the procedure; some patients, depending on the complexity of the surgery or their postoperative condition, may stay in the hospital one or two days.

Considered the most important orthopedic development in the twentieth century, arthroscopic surgery is widely used. The American Association of Orthopedic Surgeons reports that it is performed by 80% of all orthopedic surgeons. The use of arthroscopic surgery on famous athletes has been well publicized. Although arthroscopic surgery was initially only a diagnostic tool used prior to open surgery, the availability of better instruments and techniques has encouraged its use to actually treat a variety of joint problems, often avoiding more complicated surgeries with longer recovery times. New techniques under development are likely to lead to other joints, even small finger and toe joints, being treated with arthroscopic surgery in the future. Laser technology has been introduced as a treatment option in arthroscopic surgery and other advanced technologies are being explored.

Surgical procedure

After making two small incisions about the size of a buttonhole in the skin near the joint, the surgeon injects a sterile **sodium** chloride solution through one incision into the joint to expand it for better viewing and movement of the instruments. The joint area will be irrigated (flooded with fluid) to distend the joint and to remove blood and debris away from the joint for increased visibility during surgery. The arthroscope is then inserted into the second incision. While looking at the interior of the joint on the television monitor, the surgeon can determine the extent or type of injury and, if necessary, take a biopsy specimen for later pathologic examination or repair or treat the joint problem. A third tiny incision may be made in order to see other parts of the joint or to insert additional instruments, such as laser or tiny scalpels, to help make repairs to improve joint function. Arthroscopic surgery can be used to remove floating bits of cartilage, to debride (clean by removing tissue or bone) surfaces, and to treat minor tears and other disorders. When the procedure is finished, the arthroscope is removed and the joint is once again irrigated. The site of the incision is typically dressed with compression bandages (ace bandages) or absorbable sutures may be applied.

Precautions

Diagnostic or therapeutic arthroscopic surgery is not recommended unless other diagnostic procedures did not identify the joint problem or if nonsurgical treatment was unsuccessful.

Preparation

Prior to arthroscopy, the patient's medical history will be reviewed and the patient will have a complete **physical examination**. Standard preoperative blood and urine tests will be done along with diagnostic imaging scans of the affected joint such as MRI, computed tomography (CT), or arthrogram (enhanced x-ray using dye). In some cases, an **exercise** regimen or muscle stimulation treatment (transcutaneous **electrical nerve stimulation** or TENS) may be recommended to strengthen muscles around the joint prior to

WWW.BOOKBAZ.IR

surgery. Surgeons may recommend preoperative guidelines, as follows:

- Discontinue aspirin and anti-inflammatory medications two weeks before surgery.
- Stop smoking to encourage postoperative healing.
- Inform the surgeon if any fever or other illness occurs, or if cuts, scratches, or bruises appear near the surgical site before the scheduled surgery.
- Do not eat, drink, or chew gum for 12 hours prior to surgery.
- Bring crutches or a walker if hip, knee, or ankle arthroscopy is being performed.
- Wear loose-fitting clothing to allow for bulky dressings over the surgical site.

Aftercare

Immediately after the procedure, the patient will spend up to two hours in a recovery area before being discharged. Some patients may be transferred to a hospital room if the surgeon determines overnight care is necessary. The surgical site will be dressed with a compression bandage (ace bandage) or a tightly fitting stocking (support hose). An ice pack will be placed on the joint that was examined or treated by arthroscopy. This treatment may continue for up to 72 hours after surgery to keep swelling down and help prevent the formation of **blood clots**. **Pain** medication will be administered if needed, although most patients require little or no medicine for pain. Dressings can usually be removed the morning after surgery and replaced by adhesive strips. The surgeon should be notified if the patient experiences any increase in pain, swelling, redness, drainage or bleeding at the site of the surgery, signs of infection (**headache**, muscle aches, **dizziness**, **fever**), and nausea or **vomiting**.

Incision **wounds** typically heal within several days, but it may take several weeks for the joint to fully recover. Many patients can resume their daily activities within a few days after the procedure, including going back to work. Muscle strength must be regained as soon as possible after surgery to help support the affected joint. A **rehabilitation** program, including **physical therapy**, may be suggested to speed recovery and improve joint functioning. The surgeon's recommendations for recovery may include:

- Keep the surgical site and the dressings clean and dry.
- Use ice packs for up to 72 hours to reduce pain and swelling.
- Elevate the affected joint (wrist, elbow, ankle, knee) on pillows; exercise gently to encourage circulation.
- Use a knee brace or shoulder sling temporarily.
- Allow weight-bearing exercise as able.

Risks

Few complications are to be expected with arthroscopy. Those that may occur occasionally (fewer than 1% of all arthroscopies, according to the American Academy of Orthopedic Surgeons) are those associated with any invasive surgery, including infection, blood clot formation, swelling or bleeding, or damage to blood vessels or nerves. Rare instrument breakage during procedures has also been reported.

Results

Most patients undergo arthroscopic surgery as an outpatient and are home within hours or, at most, a day or two. Pain and complications are rare, and most patients experience improved mobility as they recover over a period of days, possibly with the aid of physical therapy and gentle exercise.

Some people undergoing arthroscopy may have preexisting conditions and diseases that will affect the surgical result. Recovery times will vary depending on each patient's overall condition. In some patients, certain problems may need to be treated with a combination of arthroscopic and open surgical procedures.

Alternatives

Alternatives to arthroscopic surgery include:

- avoidance of strenuous or demanding activities
- use of anti-inflammatory medications
- physical therapy and appropriate, gentle exercise, such as yoga
- use of a brace or walking aid
- glucosamine sulfate and chondroitin as nutritional supplements to help reduce pain and stiffness
- therapeutic massage, acupuncture, or other body work

REVISED BY ROSALYN CARSON-DEWITT, MD

Arthroscopy

Definition

Arthroscopy is the examination of a joint, specifically, the inside structures. The procedure is performed by inserting a specifically designed illuminated device into the joint through a small incision. This instrument is called an arthroscope. The procedure of arthroscopy is primarily associated with the process of diagnosis. However, when actual repair is performed, the procedure is called **arthroscopic surgery**.

Purpose

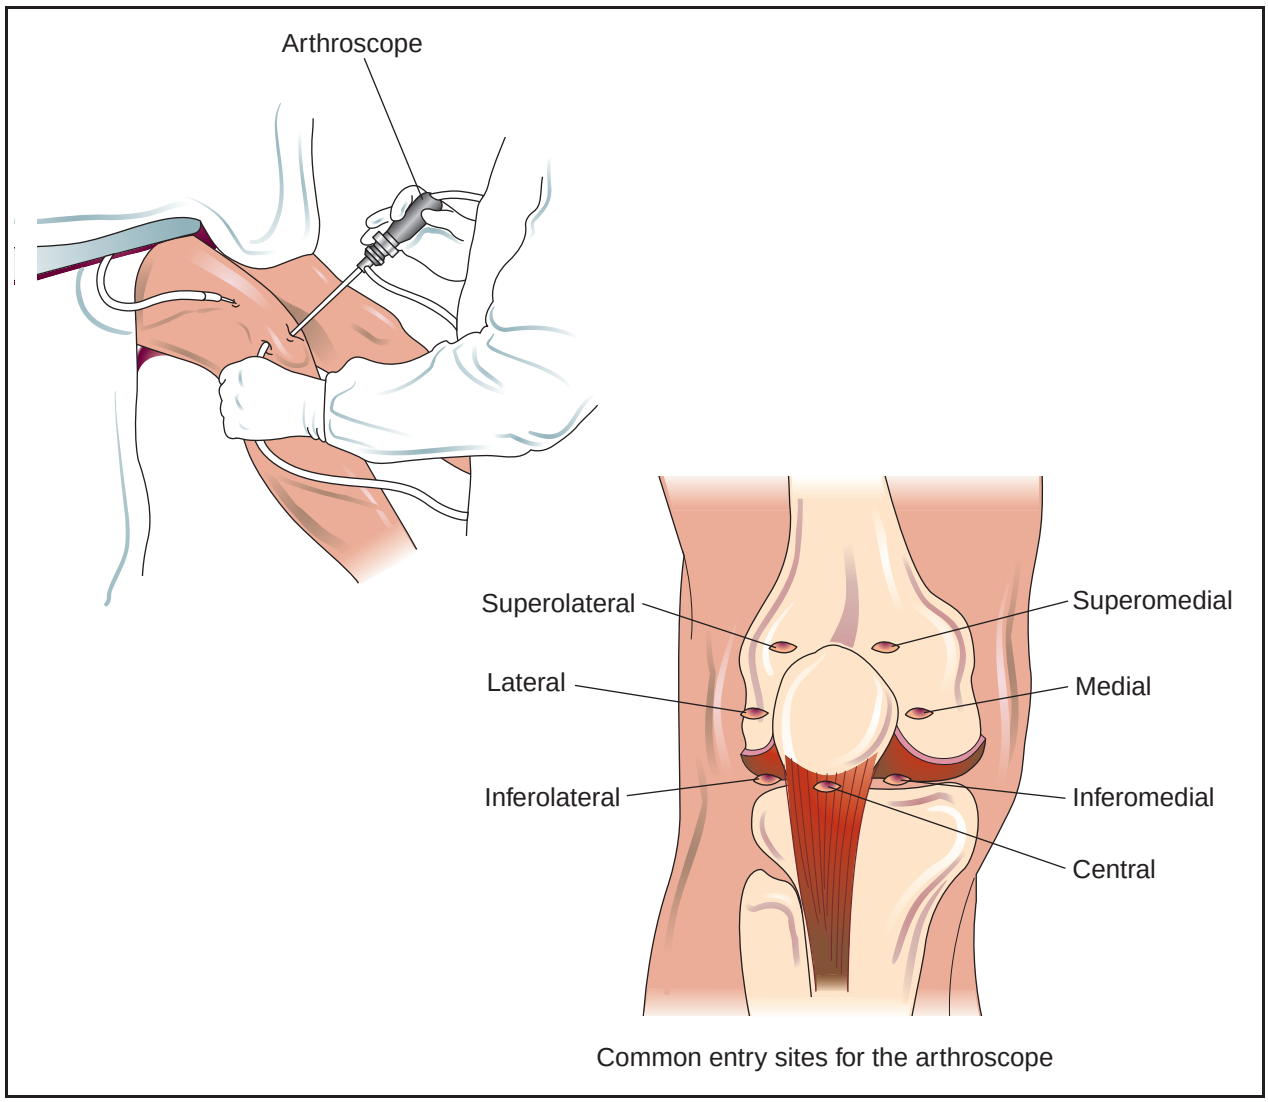
Arthroscopy is used primarily by doctors who specialize in treating disorders of the bones and related structures (orthopedics) to help diagnose joint problems. Once described as essential for those who primarily care for athletic injuries, arthroscopy is now a technique commonly used by orthopedic surgeons for the treatment of patients of all ages. This procedure is most commonly used to diagnose knee and shoulder problems, although the elbow, hip, wrist, and ankle may also be examined with an arthroscope.

A joint is a complex system. Within a joint, ligaments attach bones to other bones, tendons attach muscles to bones, cartilage lines and helps protect the ends of bones, and a special fluid (synovial fluid) cushions and lubricates the structures. Looking inside the joint allows the doctors to see exactly which structures are damaged. Arthroscopy also permits earlier diagnosis of many types of joint problems, which had been difficult to detect in previous years.

Precautions

Most arthroscopic procedures today are performed in same-day surgery centers where the patient is admitted just before surgery. A few hours following the procedure, the patient is allowed to return home, although usually someone else must drive. Depending on the type of **anesthesia** used, the patient may be told not to eat for several hours before arriving. Before the procedure, the anesthesiologist will ask if the patient has any known **allergies** to local or general anesthetics. Airway obstruction is always possible in any patient who receives a general anesthesia. Because of this, oxygen, suction, and monitoring equipment must be available. The patient's cardiac status should always be monitored in the event that any cardiac abnormalities arise during the arthroscopy.

WWW.BOOKBAZ.IR



Arthroscopy is primarily used to help diagnose joint problems. This procedure, most commonly associated with knee and shoulder problems, allows accurate examination and diagnosis of damaged joint ligaments, surfaces, and other related joint structures. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

The arthroscope is an instrument used to look directly into the joint. It contains magnifying lenses and glass-coated fibers that send concentrated light into the joint. A camera attached to the arthroscope allows the surgeon to see a clear image of the joint. This image is then transferred to a monitor located in the operating room at the time of the arthroscopy. This video technology is also important for documentation of the arthroscopic procedure. For example, if the surgeon decides after the arthroscopic examination that a conventional approach to surgically expose or "open" the joint (arthrotomy) must be used, a good photographic record will be useful when the surgeon returns to execute the final surgical plan.

The procedure requires the surgeon to make several small incisions (portals) through the skin's surface into the joint. Through one or two of the portals, a large-bore needle, called a cannula, is attached to tubing and inserted into the joint. The joint is inflated with a sterile saline solution to expand the joint and ensure clear arthroscopic viewing. Often, following a recent traumatic injury to a joint, the joint's natural fluid may be cloudy, making interior viewing of the joint difficult. In this condition, a constant flow of the saline solution is necessary. This inflow of saline

KEY TERMS

Hemarthrosis—A condition of blood within a joint.

Pulmonary embolus—Blockage of an artery of the lung by foreign matter such as fat, tumor, tissue, or a clot originating from a vein.

Thrombophlebitis—Inflamation of a vein with the formation of a thrombus or clot.

solution may be through the cannula with the outflow through the arthroscope, or the positions may be reversed. The arthroscope is placed through one of the portals to view and evaluate the condition of the joint.

Preparation

Before an arthroscopy can take place, the surgeon completes a thorough medical history and evaluation. Important for the accuracy of this diagnostic procedure, a medical history and evaluation may discover other disorders of the joint or body parts, proving the procedure unnecessary. This is always an important preliminary step, because **pain** can often be referred to a joint from another area of the body. Anatomical models and pictures are useful aids to explain to the patient the proposed arthroscopy and what the surgeon may be looking at specifically.

Proper draping of the body part is important to prevent contamination from instruments used in arthroscopy, such as the camera, light cords, and inflow and outflow drains placed in the portals. Draping packs used in arthroscopy include disposable paper gowns and drapes with adhesive backing. The surgeon may also place a tourniquet above the joint to temporarily block blood flow to the area during the arthroscopic exam.

General or local anesthesia may be used during arthroscopy. Local anesthesia is usually used because it reduces the risk of lung and heart complications and allows the patient to go home sooner. The local anesthetic may be injected in small amounts in multiple locations in skin and joint tissues in a process called infiltration. In other cases, the anesthetic is injected into the spinal cord or a main nerve supplying the area. This process is called a "block," and it blocks all sensation below the main trunk of the nerve. For example, a femoral block anesthetizes the leg from the thigh down (its name comes from femur, the thighbone). Most patients are comfortable once the skin, muscles, and other tissues around the joint are numbed by the anesthetic; however, some patients are also given a sedative if they express **anxiety** about the procedure. (It is important for the patient to remain still during the arthroscopic examination.)

General anesthesia, in which the patient becomes unconcious, may be used if the procedure may be unusually complicated or painful. For example, people who have relatively "tight" joints may be candidates for general anesthesia because the procedure may take longer and cause more discomfort.

Aftercare

The portals are closed by small tape strips or stitches and covered with dressings and a bandage. The patient spends a short amount of time in the recovery room after arthroscopy. Most patients can go home after about an hour in the recovery room. Pain medication may be prescribed for a short period; however, many patients find various over-the-counter pain relievers sufficient.

Following the surgical procedure, the patient needs to be aware of the signs of infection, which include redness, warmth, excessive pain, and swelling. The risk of infection increases if the incisions become wet too early following surgery. Because of this, it is good practice to cover the joint with plastic (for example, a plastic bag) while showering after arthroscopy.

The use of crutches is commonplace after arthroscopy, with progression to independent walking on an "as tolerated" basis by the patient. Generally, a **rehabilitation** program, supervised by a physical therapist, follows shortly after the arthroscopy to help the patient regain mobility and strength of the affected joint and limb.

Risks

The incidence of complications is low compared to the high number of arthroscopic procedures performed every year. Possible complications include infection, swelling, damage to the tissues in the joint, **blood clots** in the leg veins (**thrombophlebitis**), leakage of blood into the joint (hemarthrosis), blood clots that move to the lung (pulmonary embolus), and injury to the nerves around the joint.

Results

The goal of arthroscopy is to diagnose a joint problem causing pain and/or restrictions in normal joint function. For example, arthroscopy can be a useful tool in locating a tear in the joint surface of the knee or locating a torn ligament of the shoulder. Arthroscopic examination is often followed by arthroscopic surgery performed to repair the problem with

WWW.BOOKBAZ.IR

appropriate arthroscopic tools. The final result is to decrease pain, increase joint mobility, and thereby improve the overall quality of the patient's activities of daily living.

Abnormal results

Less optimal results that may require further treatment include adhesive capsulitis. In this condition, the joint capsule that naturally forms around the joint becomes thickened, forming **adhesions**. This results in a stiff and less mobile joint. This problem is frequently corrected by manipulation and mobilization of the joint with the patient placed under general anesthesia.

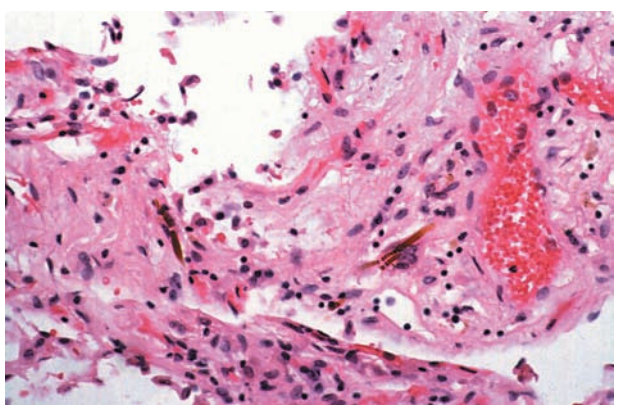
Asbestosis

Definition

Asbestosis is chronic, progressive inflammation of the lung. It is not contagious.



Micrograph of asbestos fibers embedded in lung tissue. *(Custom Medical Stock Photo, Inc.)*

Description

Asbestosis is a consequence of prolonged exposure to large quantities of asbestos, a material once widely used in construction, insulation, and manufacturing. When asbestos is inhaled, fibers penetrate the breathing passages and irritate, fill, inflame, and scar lung tissue. In advanced asbestosis, the lungs shrink, stiffen, and become honeycombed (riddled with tiny holes).

Legislation has reduced use of asbestos in the United States, but workers who handle automobile brake shoe linings, boiler insulation, ceiling acoustic tiles, electrical equipment, and fire-resistant materials are still exposed to the substance. Asbestos is used in the production of paints and plastics. Significant amounts can be released into the atmosphere when old buildings or boats are razed or remodeled.

Asbestosis is most common in men over 40 who have worked in asbestos-related occupations. Smokers or heavy drinkers have the greatest risk of developing this disease. According to the Centers for Disease Control and Prevention, between 1999 and 2005, more than 18,000 Americans over the age of 25 died as a result of asbestosis. The death rate increased from 2,482 deaths in 1999 to 2,704 in 2005, an increase of 222 deaths. Men are diagnosed with **mesothelioma** more often than women, and males comprised 80.8% of mesothelioma deaths during this timeframe (a total of 14,591). White people comprised 95.1% of mesothelioma deaths, totaling 17,180. Age influenced the mortality rate, as those 75 years old and older comprised the majority of the patients who passed away from mesothelioma (8,858 total deaths). Deaths in patients age 44 or younger totaled 311, or 1.7%.

Causes and symptoms

Occupational exposure is the most common cause of asbestosis, but the condition also strikes people who inhale asbestos fiber or who are exposed to waste products from plants near their homes. Family members can develop the disease as a result of inhaling particles of asbestos dust that cling to workers' clothes.

It is rare for asbestosis to develop in anyone who hasn't been exposed to large amounts of asbestos on a regular basis for at least 10 years. Symptoms of the disease do not usually appear until 15–20 years after initial exposure to asbestos.

The first symptom of asbestosis is usually **shortness of breath** following **exercise** or other physical

KEY TERMS

Asbestos—A silicate (containing silica) mineral that occurs in a variety of forms; it is characterized by a fibrous structure and resistance to fire.

activity. The early stages of the disease are also characterized by a dry **cough** and a generalized feeling of illness.

As the disease progresses and lung damage increases, shortness of breath occurs even when the patient is at rest. Recurrent respiratory infections and coughing up blood are common. So is swelling of the feet, ankles, or hands. Other symptoms of advanced asbestosis include chest **pain**, hoarseness, and restless sleep. Patients who have asbestosis often have clubbed (widened and thickened) fingers. Other potential complications include **heart failure**, collapsed (deflated) lung, and **pleurisy** (inflammation of the membrane that protects the lung).

Diagnosis

Screening of at-risk workers can reveal lung inflammation and lesions characteristic of asbestosis. Patients' medical histories can identify occupations, hobbies, or other situations likely to involve exposure to asbestos fibers.

X rays can show shadows or spots on the lungs or an indistinct or shaggy outline of the heart that suggests the presence of asbestosis. Blood tests are used to measure concentrations of oxygen and carbon dioxide. **Pulmonary function tests** can be used to assess a patient's ability to inhale and exhale, and a computed tomography scan (CT) of the lungs can show flat, raised patches associated with advanced asbestosis.

Treatment

The goal of treatment is to help patients breathe more easily, prevent colds and other respiratory infections, and control complications associated with advanced disease. Ultrasonic, cool-mist humidifiers or controlled coughing can loosen bronchial secretions.

Regular exercise helps maintain and improve lung capacity. Although temporary bed rest may be recommended, patients are encouraged to resume their regular activities as soon as they can.

Anyone who develops symptoms of asbestosis should see a family physician or lung disease specialist. A doctor should be notified if someone who has been diagnosed with asbestosis:

- coughs up blood
- continues to lose weight
- is short of breath
- has chest pain
- develops a sudden fever of 101°F (38.3°C) or higher
- develops unfamiliar, unexplained symptoms

Prognosis

Asbestosis can't be cured, but its symptoms can be controlled. Doctors don't know why the health of some patients deteriorates and the condition of others remain the same, but believe the difference may be due to varying exposures of asbestos. People with asbestosis who smoke, particularly those who smoke more than one pack of cigarettes each day, are at increased risk for developing lung cancer and should be strongly advised to quit **smoking**.

Prevention

Workers in asbestosis-related industries should have regular x rays to determine whether their lungs are healthy. A person whose lung x ray shows a shadow should eliminate asbestos exposure even if no symptoms of the condition have appeared.

Anyone who works with asbestos should wear a protective mask or a hood with a clean-air supply and obey recommended procedures to control asbestos dust. Anyone who is at risk of developing asbestosis should:

- not smoke
- be vaccinated against influenza and pneumonia
- exercise regularly to maintain cardiopulmonary fitness
- avoid crowds and people who have respiratory infections

A person who has asbestosis should exercise regularly, relax, and conserve energy whenever necessary.

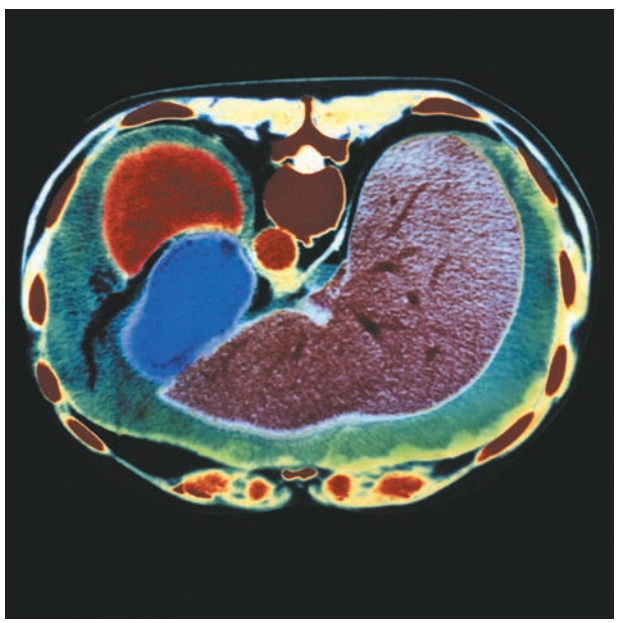
Ascites

Definition

Ascites is an abnormal accumulation of fluid in the abdomen.

Description

Rapidly developing (acute) ascites can occur as a complication of **trauma**, perforated ulcer, **appendicitis**, or inflammation of the colon or other tube-shaped organ (**diverticulitis**). This condition can also develop when intestinal fluids, bile, pancreatic juices, or bacteria invade or inflame the smooth, transparent membrane that lines the inside of the abdomen (peritoneum). However, ascites is more often associated with **liver disease** and other long-lasting (chronic) conditions.



A computed tomography (CT) scan of an axial section through the abdomen, showing ascites. At right is the liver occupying much of the abdomen; the stomach and spleen are also seen. Around these organs is fluid giving rise to this condition. *(Custom Medical Stock Photo, Inc.)*

Types of ascites

Cirrhosis, which is responsible for 80% of all instances of ascities in the United States, triggers a series of disease-producing changes that weaken the kidney's ability to excrete **sodium** in the urine.

Pancreatic ascites develops when a cyst that has thick, fibrous walls (pseudocyst) bursts and permits pancreatic juices to enter the abdominal cavity.

Chylous ascites has a milky appearance caused by lymph that has leaked into the abdominal cavity. Although chylous ascites is sometimes caused by trauma, abdominal surgery, **tuberculosis**, or another peritoneal infection, it is usually a symptom of lymphoma or some other cancer.

Cancer causes 10% of all instances of ascites in the United States. It is most commonly a consequence of disease that originates in the peritoneum (peritoneal carcinomatosis) or of cancer that spreads (metastasizes) from another part of the body.

Endocrine and renal ascites are rare disorders. Endocrine ascites, sometimes a symptom of an endocrine system disorder, also affects women who are taking fertility drugs. Renal ascites develops when blood levels of albumin dip below normal. Albumin is the major protein in blood plasma. It functions to keep fluid inside the blood vessels.

Causes and symptoms

Causes

The two most important factors in the production of ascites due to chronic liver disease are:

- Low levels of albumin in the blood that cause a change in the pressure necessary to prevent fluid exchange (osmotic pressure). This change in pressure allows fluid to seep out of the blood vessels.
- An increase in the pressure within the branches of the portal vein that run through liver (portal hypertension). Portal hypertension is caused by the scarring that occurs in cirrhosis. Blood that cannot flow through the liver because of the increased pressure leaks into the abdomen and causes ascites.

Other conditions that contribute to ascites development include:

- hepatitis
- heart or kidney failure
- inflammation and fibrous hardening of the sac that contains the heart (constrictive pericarditis)

Persons who have **systemic lupus erythematosus** but do not have liver disease or portal **hypertension**

KEY TERMS

Computed tomography scan (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Interferon—A protein formed when cells are exposed to a virus. Interferon causes other noninfected cells to develop translation inhibitory protein (TIP). TIP blocks viruses from infecting new cells.

Paracentesis—A procedure in which fluid is drained from a body cavity by means of a catheter placed through an incision in the skin.

Systemic lupus erythematosus—An inflammatory disease that affects many body systems, including the skin, blood vessels, kidneys, and nervous system. It is characterized, in part, by arthritis, skin rash, weakness, and fatigue.

Ultrasonography—A test using sound waves to measure blood flow. Gel is applied to a hand-held transducer that is pressed against the patient's body. Images are displayed on a monitor.

occasionally develop ascites. Depressed thyroid activity sometimes causes pronounced ascites. Inflammation of the pancreas (**pancreatitis**) rarely causes significant accumulations of fluid.

Symptoms

Small amounts of fluid in the abdomen do not usually produce symptoms. Massive accumulations may cause:

- rapid weight gain
- abdominal discomfort and distention
- shortness of breath
- swollen ankles

Diagnosis

Skin stretches tightly across an abdomen that contains large amounts of fluid. The navel bulges or lies flat, and the fluid makes a dull sound when the doctor taps the abdomen. Ascitic fluid may cause the flanks to bulge.

Physical examination generally enables doctors to distinguish ascities from **pregnancy**, intestinal gas, **obesity**, or ovarian tumors. **Ultrasound** or **computed tomography scans** (CT) can detect even small amounts of fluid. Laboratory analysis of fluid extracted by inserting a needle through the abdominal wall (diagnostic **paracentesis**) can help identify the cause of the accumulation.

Treatment

Reclining minimizes the amount of salt the kidneys absorb, so treatment generally starts with bed rest and a low-salt diet. Urine-producing drugs (**diuretics**) may be prescribed if initial treatment is ineffective. The weight and urinary output of patients using diuretics must be carefully monitored for signs of:

- hypovolemia (massive loss of blood or fluid)
- azotemia (abnormally high blood levels of nitrogen-bearing materials)
- potassium imbalance
- high sodium concentration. If the patient consumes more salt than the kidneys excrete, increased doses of diuretics should be prescribed

Moderate-to-severe accumulations of fluid are treated by draining large amounts of fluid (large-volume paracentesis) from the patient's abdomen. This procedure is safer than diuretic therapy. It causes fewer complications and requires a shorter hospital stay.

Large-volume paracentesis is also the preferred treatment for massive ascites. Diuretics are sometimes used to prevent new fluid accumulations, and the procedure may be repeated periodically.

Alternatives

Dietary alterations, focused on reducing salt intake, should be a part of the treatment. In less severe cases, herbal diuretics like dandelion (*Taraxacum officinale*) can help eliminate excess fluid and provide potassium. Potassium-rich foods like low-fat yogurt, mackerel, cantaloupe, and baked potatoes help balance excess sodium intake.

Prognosis

The prognosis depends upon the condition that is causing the ascites. Carcinomatous ascites has a very bad prognosis. However, salt restriction and diuretics can control ascites caused by liver disease in many cases.

Therapy should also be directed towards the underlying disease that produces the ascites. Cirrhosis should be treated by abstinence from alcohol and appropriate diet. The new interferon agents maybe helpful in treating chronic hepatitis.

WWW.BOOKBAZ.IR

Prevention

Modifying or restricting use of salt can prevent most cases of recurrent ascites.

Aspartate aminotransferase test

Definition

The aspartate aminotransferase test measures levels of aspartate aminotransferase (AST), an enzyme released into the blood when certain organs or tissues, particularly the liver and heart, are injured. Aspartate aminotransferase is also known as serum glutamic oxaloacetic transaminase (SGOT).

Purpose

The determination of AST levels aids primarily in the diagnosis of **liver disease**. In the past, the AST test was used to diagnose **heart attack** (myocardial infarction or MI), but more accurate blood tests have largely replaced it for cardiac purposes.

Description

AST is determined by analysis of a blood sample, usually taken from a venipuncture site at the bend of the elbow.

KEY TERMS

Cirrhosis—Disease of the liver caused by chronic damage to its cells.

Myocardial infarction—Commonly known as a heart attack; sudden death of part of the heart muscle characterized, in most cases, by severe, unremitting chest pain.

AST is found in the heart, liver, skeletal muscle, kidney, pancreas, spleen, lung, red blood cells, and brain tissue. When disease or injury affects these tissues, the cells are destroyed and AST is released into the bloodstream. The amount of AST is directly related to the number of cells affected by the disease or injury, but the level of elevation depends on the length of time that the blood is tested after the injury. Serum AST levels become elevated 8 hours after cell injury, peak at 24–36 hours, and return to normal in three to seven days. If the cellular injury is chronic (ongoing), AST levels will remain elevated.

One of the most important uses for AST determination has formerly been in the diagnosis of a heart attack. AST can assist in determining the timing and extent of a recent MI, although it is less specific than creatine phosphokinase (CPK), CK-MB, myoglobin, troponin, and lactic dehydrogenase (LDH). Assuming no further cardiac injury occurs, the AST level rises within 6–10 hours after an acute attack, peaks at 12–48 hours, and returns to normal in three to four days. Myocardial injuries such as **angina** (chest **pain**) or **pericarditis** (inflammation of the pericardium, the membrane around the heart) do not increase AST levels.

AST is also a valuable aid in the diagnosis of liver disease. Although not specific for liver disease, it can be used in combination with other enzymes to monitor the course of various liver disorders. Chronic, silent hepatitis (**hepatitis C**) is sometimes the cause of elevated AST. In **alcoholic hepatitis**, caused by excessive alcohol ingestion, AST values are moderately elevated; in acute viral hepatitis, AST levels can rise to over 20 times the normal amount. Acute extrahepatic (outside the liver) obstruction, such as **gallstones**, produces AST levels that can quickly rise to 10 times normal, and then rapidly fall. In cases of **cirrhosis**, the AST level is related to the amount of active inflammation of the liver. Determination of AST also assists in early recognition of toxic hepatitis, which results from exposure to drugs toxic to the liver, like **acetaminophen** and cholesterol-lowering medications.

Other disorders or diseases in which the AST determination can be valuable include acute **pancreatitis**, muscle disease, **trauma**, severe **burns**, and **infectious mononucleosis**.

Preparation

The physician may require discontinuation of any drugs that might affect the test. These include **antihypertensive drugs** (for treatment of high blood pressure), coumarin-type anticoagulants (blood-thinning drugs), digitalis, erythromycin (an antibiotic), **oral contraceptives**, and opiates, among others. The patient may also need to cut back on strenuous activities temporarily, because **exercise** can elevate AST for a day or two.

Aftercare

This test involves blood being drawn, usually from a vein in the elbow. The person being tested should keep the wound from the needle puncture covered (with a bandage) until the bleeding stops. Individuals should report any unusual symptoms to their physician.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

Normal ranges for the AST are laboratory-specific, but can range from 3–45 units/L (units per liter).

Abnormal results

Striking elevations of AST (400–4000 units/L) are found in almost all forms of acute hepatic **necrosis**, such as viral hepatitis and carbon tetrachloride **poisoning**. In alcoholics, even moderate doses of the analgesic acetaminophen have caused extreme elevations (1,960–29,700 units/L). Moderate rises of AST are seen in **jaundice**, cirrhosis, and metastatic carcinoma. Approximately 80% of patients with infectious mononucleosis show elevations in the range of 100–600 units/L.

REVISED BY L. FLEMING FALLON, JR., MD, DRPH

Asperger syndrome

Definition

Asperger syndrome (AS), which is also called Asperger disorder or autistic psychopathy, belongs to a group of childhood disorders known as **pervasive developmental disorders** (PDDs) or autistic spectrum disorders. AS was first described by Hans Asperger, an Austrian psychiatrist, in 1944. Asperger's work was unavailable in English before the mid-1970s; as a

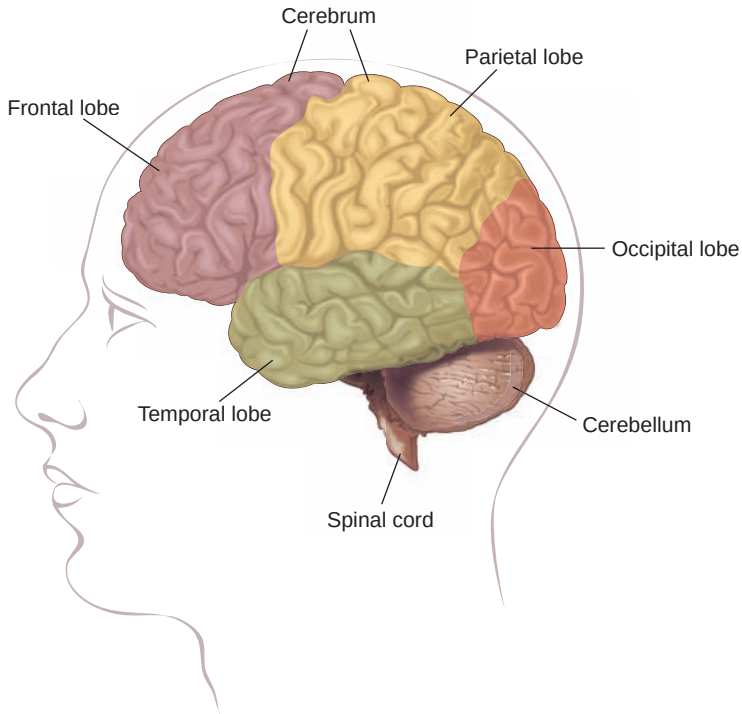
WWW.BOOKBAZ.IR

Brain abnormalities associated with Asperger syndrome

Polymicrogyria (PMG) is a developmental brain malformation characterized by an excessive number of small folds (gyri) on the surface of the brain.

Macrogyria is the congenital condition of having an enlarged brain.

Specific malformations that have been associated with Asperger syndrome include left frontal macrogyria, bilateral opercular polymicrogyria, left temporal lobe damage, and left parieto occipital hypoperfusion.



Possible brain malformations associated with Asperger syndrome. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

result, AS was often unrecognized in English-speaking countries until the late 1980s. Before the fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*, 1994), there was no official definition of AS.

Demographics

According to the National Institute of Neurological Disorders and Stroke (NINDS), the rate of occurrence of AS is not well established. Estimates range from two out of every 10,000 children to one out of every 300, with boys affected up to four times more frequently than girls. Further research is required to obtain precise AS prevalence data. In addition, little research has been done on the populations of developing countries, and no information is available about the incidence of the disorder in different racial or ethnic groups.

Description

Children with AS learn to talk at the usual age and often have above-average verbal skills. They have normal or above-normal intelligence and the ability to take care of themselves. The distinguishing features of AS are problems with social interaction, particularly reciprocating and empathizing with the feelings of others; difficulties with nonverbal communication (e.g., facial expressions); peculiar speech habits that include repeated words or phrases and a flat, emotionless vocal tone; an apparent lack of common sense; a fascination with obscure or limited subjects (e.g., doorknobs, railroad schedules, astronomical data, etc.), often to the exclusion of other interests; clumsy and awkward physical movements; and odd or eccentric behaviors, such as hand wringing or finger flapping, swaying or other repetitious whole-body movements, or watching spinning objects for long periods of time.

Risk factors

There is some indication that AS runs in families, particularly in families with histories of depression and **bipolar disorder**. Asperger noted that his initial group of patients had fathers with AS symptoms. Knowledge of the genetic profile as a risk factor continues to be limited.

Causes and symptoms

Asperger syndrome seems to run in families. Imaging studies have revealed differences in the structure

and function of brain tissue. These changes appear to occur during embryonic brain development. As with **autism**, associations have been made between Asperger syndrome and a number of genes, many of which direct the formation of brain tissue and the communication between brain cells. A variety of environmental causes have also been postulated as causing Asperger syndrome, including advanced parental age, pesticides, and exposure to valproic acid (a seizure medication), though none of these have been proven. As with autism, although there has been popular uproar regarding a possible association between immunizations and the disorder, this association has been disproved. The research article that put forward this hypothesis has been publicly discredited, and a retraction has been printed.

In young children, the symptoms of AS typically include problems picking up social cues and understanding the basics of interacting with other children. These children may want friendships but find themselves unable to make friends. Most children with Asperger are diagnosed during the elementary school years, because the symptoms of the disorder become more apparent at this point. They include:

- poor pragmatic language skills, such as using incorrect tone or volume of voice for specific contexts or failing to understand the appropriate uses of humorous or slang expressions within social contexts
- problems with hand-eye coordination and other visual skills
- problems making eye contact with others
- learning difficulties, which may range from mild to severe
- tendency to become absorbed in a particular topic and not know when others are bored with the conversation
- repetitive behaviors, such as counting a group of coins or marbles over and over, reciting the same song or poem several times, or buttoning and unbuttoning a jacket repeatedly

Adolescence is one of the most painful periods for young people with Asperger because social interactions are more complex in this age group and require more subtle social skills. Some boys with AS become frustrated while trying to relate to their peers and may become aggressive. Both boys and girls with the disorder are often quite naive for their age and easily manipulated by street-wise classmates. They are also more vulnerable than most youngsters to peer pressure.

Less research has been done regarding adults with AS. Some have serious difficulties with social and occupational functioning, but others are able to finish their schooling, join the workforce, and marry and have families.

KEY TERMS

Autistic psychopathy—Hans Asperger's original name for Asperger syndrome. It is still used occasionally as a synonym for the disorder.

Gillberg's criteria—A six-item checklist for Asperger syndrome developed by Christopher Gillberg, a Swedish researcher. It is widely used as a diagnostic tool.

High-functioning autism (HFA)—A subcategory of autistic disorder consisting of children diagnosed with IQs of 70 or higher.

Nonverbal learning disability (NLD)—A learning disability syndrome identified in 1989 that may overlap with some of the symptoms of Asperger syndrome.

Pervasive developmental disorder (PDD)—Used by the American Psychiatric Association for individuals who meet some but not all of the criteria for autism.

Diagnosis

As of 2014, there were no blood tests or brain scans that could be used to diagnose AS. Until *DSM-IV* (1994), there was no "official" list of symptoms for the disorder, which made its diagnosis both difficult and inexact. Although most children with AS are diagnosed between five and nine years of age, many are not diagnosed until adulthood. Misdiagnoses are common; AS has been confused with such other neurological disorders as **Tourette syndrome** or with **attention deficit hyperactivity disorder (ADHD)**, **oppositional defiant disorder** (ODD), or **obsessive-compulsive disorder** (OCD). Some researchers think that AS overlaps some types of learning disability, such as the nonverbal learning disability (NLD) syndrome identified in 1989.

The inclusion of AS as a separate diagnostic category in *DSM-IV* was justified on the basis of a large international field trial of over one thousand children and adolescents. Nevertheless, the diagnosis of AS is also complicated by confusion with such other diagnostic categories as high-functioning (IQ 70) autism (HFA), and schizoid personality disorder of childhood. With regard to the latter, AS is not an

WWW.BOOKBAZ.IR

unchanging set of personality traits but has a developmental dimension. AS is distinguished from HFA by the following characteristics:

- later onset of symptoms (usually around three years of age)
- early development of grammatical speech; the AS child's verbal IQ is usually higher than performance IQ (the reverse being the case in children with autism)
- less severe deficiencies in social and communication skills
- presence of intense interest in one or two topics
- physical clumsiness and lack of coordination
- family history of the disorder
- lower frequency of neurological disorders
- more positive outcome in later life

DSM-IV criteria for Asperger syndrome

DSM-IV specifies six diagnostic criteria for AS:

- The child's social interactions are impaired in at least two of the following ways: markedly limited use of nonverbal communication; lack of age-appropriate peer relationships; failure to share enjoyment, interests, or accomplishment with others; lack of reciprocity in social interactions.
- The child's behavior, interests, and activities are characterized by repetitive or rigid patterns, such as an abnormal preoccupation with one or two topics, or with parts of objects; repetitive physical movements; or rigid insistence on certain routines and rituals.
- The child's social, occupational, or educational functioning is significantly impaired.
- The child has normal age-appropriate language skills.
- The child has normal age-appropriate cognitive skills, self-help abilities, and curiosity about the environment.
- The child does not meet criteria for another specific PDD or schizophrenia.

Other diagnostic scales and checklists

Other instruments that have been used to identify children with AS include Gillberg's criteria, a six-item list compiled by a Swedish researcher that specifies problems in social interaction, a preoccupying narrow interest, forcing routines and interests on the self or others, speech and language problems, nonverbal communication problems, and physical clumsiness; and the Australian Scale for Asperger Syndrome, a detailed multi-item questionnaire developed in 1996.

Brain imaging findings

As of 2014, only a few structural abnormalities of the brain had been linked to AS. Findings include abnormally large folds in the brain tissue in the left frontal region, abnormally small folds in the operculum (a lid-like structure composed of portions of three adjoining brain lobes), and damage to the left temporal lobe. The first single photon emission tomography (SPECT) study of a patient with AS found a lower than normal blood supply in the left parietal area of the brain. Brain imaging studies on a larger sample of patients is the next stage of research.

Diagnostic coding changes in DSM-5

The diagnosis of Asperger syndrome has been complicated by its close relationship to the symptoms found in people with autistic disorders. As a result, researchers have had a great deal of difficulty determining prevalence and incidence statistics for Asperger syndrome, and clinicians have had difficulty accessing services for their patients. After re-evaluating the diagnostic criteria for AS, autism, and other related disorders, the panel charged with creating the fifth edition of the *DSM* (*DSM-5*), combines the diagnoses of Asperger syndrome, autism, childhood disintegrative disorder, and pervasive developmental disorder under the rubric of autism spectrum disorders. This change in the diagnostic coding has led to some controversy and will also lead to changes in the prevalence and incidence statistics for all of the affected disorders. The new categorization, however, may have the advantage of improved diagnostic consistency, with accompanying improvement in accessibility of services.

Treatment

There is no cure for AS and no single prescribed regimen for all affected patients. Specific treatments are based on the individual's symptom pattern.

Traditional

Individuals with Asperger syndrome often benefit from **psychotherapy**, particularly during adolescence, in order to help them cope with depression and other painful feelings related to their social difficulties. Treatment aims to help patients manage the major issues associated with the condition: lack of communication skills, obsessive routines, and physical clumsiness.

Therapists who are experienced in treating children with AS have found that the child should be allowed to proceed slowly in forming an emotional

bond with the therapist. Too much emotional intensity at the beginning may be more than the child can handle. Behavioral approaches seem to work best with these children. Play therapy can be helpful in teaching the child to recognize social cues as well as lowering the level of emotional tension.

Communication and social skills training groups are also often used to help children with Asperger syndrome learn and then practice skills that may benefit them in the classroom, within their families, and in their efforts to connect to their peers.

Adults with AS are most likely to benefit from individual therapy using a cognitive-behavioral approach, although many also attend **group therapy**. Some adults have been helped by working with speech therapists on their pragmatic language skills. A relatively new approach called behavioral coaching has been used to help adults with AS learn to organize and set priorities for their daily activities.

Drugs

The drugs that are recommended most often for children with AS are psychostimulants (methylphenidate, pemoline), clonidine, or one of the tricyclic antidepressants (TCAs) for hyperactivity or inattention; **beta blockers**, neuroleptics, or lithium for anger, aggression, agitation, and irritability; **selective serotonin reuptake inhibitors** (SSRIs) or TCAs for rituals, repetitive behavior, depression, and preoccupations; and SSRIs or TCAs for **anxiety** and OCD-like symptoms. Low-dose naltrexone (a drug usually used to help alcoholics avoid drinking) has been shown to be useful in decreasing ritualistic, repetitive behaviors in people with Asperger syndrome. One alternative herbal remedy that has been tried with AS patients is St. John's wort.

Clinical trials

In 2014, at least 58 clinical trials pertaining to Asperger syndrome were being sponsored by the National Institutes of Health (NIH) and other agencies.

One study (trial no. NCT00464477) was recruiting parents of children with a pervasive developmental disorder (including autism, autistic spectrum disorder, PDD-NOS, Asperger syndrome, childhood disintegrative disorder, and Rett syndrome) to participate in a study seeking to determine potential causes of these disorders. Other trials were evaluating drugs for treatment. For example, N-acetylcysteine was being tested for the improvement of the behavior problems often associated with autism spectrum disorders (NCT00453180). The potential beneficial effect of DMSA, an oral chelating agent that removes mercury and other metals from the body, was also being investigated (NCT00376194), as was the efficacy of risperidone in normalizing symptoms (NCT00352196). Other drugs being tested were aripiprazole (NCT00198055) and citalopram (NCT00086645). A **cognitive-behavioral therapy** (CBT) program was also being evaluated for treating anxiety symptoms, social problems, and adaptive behavior deficits in children with Asperger syndrome (NCT00280670).

Prognosis

AS is a lifelong but stable condition. The prognosis for children with AS is generally good as far as intellectual development is concerned, though one challenge is equipping schools with the tools needed to meet special social needs. However, there is an increased risk of developing **psychosis** later in life.

Prevention

Effective prevention of Asperger syndrome awaits further genetic mapping together with ongoing research in the structures and functioning of the brain.

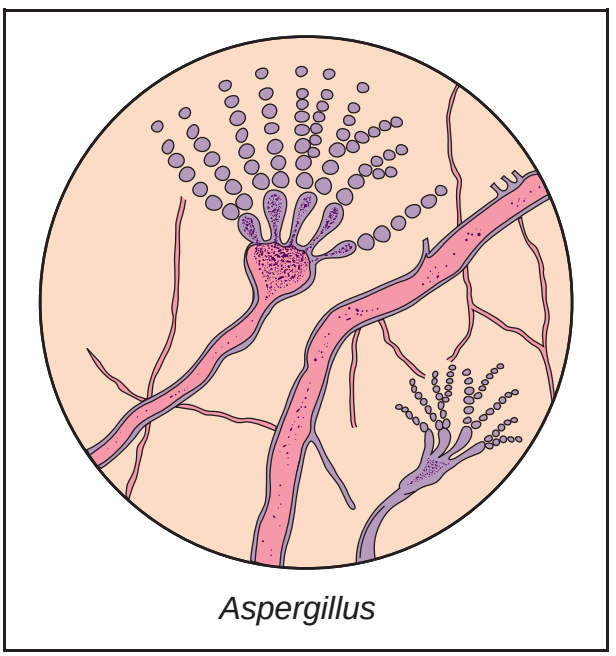
Aspergilloma *see* **Aspergillosis**

Aspergillosis

Definition

Aspergillosis refers to several forms of disease caused by a fungus in the genus *Aspergillus*. Aspergillosis **fungal infections** can occur in the ear canal, eyes, nose, sinus cavities, and lungs. In some individuals, the



Aspergillosis is an infection of the lungs caused by inhalation of airborne spores of the fungus *Aspergillus*. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

infection can invade bone and the membranes (meninges) that enclose the brain and spinal cord and cause **meningitis**.

Description

Aspergillosis is primarily an infection of the lungs caused by the inhalation of airborne spores of the fungus *Aspergillus*. Spores are the small particles that most fungi use to reproduce.

Aspergillosis can be a serious, potentially deadly threat for two primary reasons:

- Aspergillosis usually occurs in those individuals who are already ill or have weakened immune systems, such as patients who have undergone chemotherapy for cancer or those infected with HIV.
- None of the currently available antifungal drugs are reliably effective against *Aspergillus*.

Once aspergillosis was considered rare. The incidence of reported aspergillosis has risen with the development of more sophisticated methods of diagnosis. In addition, advances such as with the increased use of certain immunosuppressant chemotherapeutic and corticosteroid drugs that are effective in treating cancers but that decrease the individual's immune response, and individuals with HIV/AIDS living longer with better drug therapies, more individuals are susceptible to diseases such aspergillosis that attack when the immune system is suppressed.

Risk factors

Although virtually everyone is exposed to the fungi that cause this disease in their daily environment, most people do not contract the disease. When *Aspergillus* does cause disease, however, it usually occurs in individuals with weakened immune systems (immunocompromised) or who have a history of respiratory ailments. Because aspergillosis does not present distinctive it is thought to be under diagnosed and under reported. Furthermore, many patients with the more severe forms of aspergillosis tend to have multiple, complex health problems, such as HIV/AIDS or a blood disorder such as leukemia, which can further complicate diagnosis and treatment.

The ability to perform advanced tissue and organ transplants has increased the number of people vulnerable to all fungal infections. Transplant recipients, particularly those receiving bone marrow or heart transplants, are highly susceptible to *Aspergillus*, which may be circulating in the hospital air.

Demographics

Aspergillosis is rare, with the United States Centers for Disease Control and Prevention (CDC) estimating that there are one to two cases per 100,000 people each year in the United States. However, this number might be an underestimate of the prevalence of the disease because hospitals are not required to report this kind of fungal infection to any national tracking body. It occurs more common in individuals who have compromised immune systems, such as transplant recipients and individuals with **AIDS**. Few international statistics are available, although prevalence in the United Kingdom appears to be higher than in the United States.

Causes and symptoms

Airborne *Aspergillus* spores enter the body primarily through inhalation but can also lodge in the ear or eye. Normally functioning immune systems are generally able to cope without consequent development of aspergillosis.

It is important to make distinctions between the various forms of aspergillosis, as the treatment and prognosis varies considerably among types. Aspergillosis as a diagnosis refers to three general forms:

- Allergic bronchopulmonary aspergillosis (ABPA) is seen in patients with long-standing asthma, particularly in patients taking oral corticosteroids for a long time. This is usually the least serious and most treatable form.
- Aspergilloma refers to the mass formed when fungal spores settle into or colonize areas of the lung that have been pitted and scarred as a result of tuberculosis or prior pneumonia. There are several available treatments, although the success rate varies with each treatment.
- Invasive fungal infection refers to rare cases in which the fungus spreads throughout the body via the bloodstream and invades other organ systems. Once established, invasive fungal infections are extremely difficult to cure and, as a result, the associated death rate is extremely high.

Symptoms of aspergillosis are nonspecific and include **fever**, **cough**, and coughing up mucus. Symptoms do not improve with antibiotic therapy.

Diagnosis

Aspergillosis can be quite difficult to diagnose because the symptoms, such as coughing and **wheezing**, if present at all, are common to many respiratory disorders. Furthermore, blood and sputum cultures

WWW.BOOKBAZ.IR

are not very helpful. The presence of *Aspergillus* is so common, even in asthmatics, that a positive culture alone is insufficient for a diagnosis. Other, potentially more useful, screening tools include examining the sample obtained after repeatedly washing the bronchial tubes of the lung with water (bronchial lavage), but examining a tissue sample (biopsy) is the most reliable diagnostic tool. As of 2014, researchers were attempting to develop a practical, specific, and rapid blood test that would confirm *Aspergillus* infection.

Signs of allergic bronchopulmonary aspergillosis(ABPA) include a worsening of bronchial **asthma** accompanied by a low-grade fever. Brown flecks or clumps may be seen in the sputum. **Pulmonary function tests** may show decreased blood flow, suggesting an obstruction within the lungs. Elevated blood levels of an antibody produced in response to *Aspergillus* and of certain immune system cells may indicate a specific allergic-type immune system response.

A fungal mass (aspergilloma) in the lung usually does not produce clear symptoms and is generally diagnosed when seen on chest x rays. However, 70% or more of patients spit up blood from the lungs (**hemoptysis**) at least once, and this may become repetitive and serious. Hemoptysis, then, is another indication that the patient may be suffering from an aspergilloma.

In individuals with suppressed immune systems who are at risk for developing invasive aspergillosis, the physician may use a combination of **blood culture** with visual diagnostic techniques, such as **computed tomography scans** (CT) and radiography, to arrive at a likely diagnosis.

Treatment

Fungal infection by *Aspergillus* presents a major challenge, particularly in the patient with a suppressed immune system (immunocompromised). Hospitals and government health agencies continually seek ways to minimize exposure for hospitalized patients. Practical suggestions are minimal but include moving leaf piles away from the house. Unfortunately, overall avoidance of this fungus is all but impossible because it is present in the environment virtually everywhere. Research efforts are being directed at enhancing patients' resistance to *Aspergillus* rather than trying to eliminate exposure to the fungus. Given the growing number of people with immune disorders or whose immune systems have been suppressed in the course of treating another disease, research and clinical trials for new antifungal agents will be increasingly important in the future.

The treatment method selected depends on the form of aspergillosis. ABPA can usually be treated with many of the same drugs used to treat asthma, such as systemic **steroids**. Long-term therapy may be required, however, to prevent recurrence. Antifungal agents are not recommended in the treatment of ABPA.

In cases of aspergilloma, it may become necessary to surgically remove or reduce the size of a fungal mass, especially if the patient continues to spit up blood. In aspergillosis cases affecting the nose and nasal sinuses, surgery may also be required.

In non-ABPA cases, the use of antifungal drugs may be indicated. In such cases, amphotericin B (Fungizone) is the first-line therapy. The prescribed dose will depend on the patient's condition but usually begins with a small test dose and then escalates. Less than one-third of patients are likely to respond to amphotericin B, and its side effects often limit its use. For patients who do not respond to oral amphotericin B, another option is a different formulation of the same drug called liposomal amphotericin B.

For patients who fail to respond or who cannot tolerate amphotericin B, another drug called itraconazole (Sporanox), given 400–600 mg daily, has also been approved. Treatment generally lasts about three months. Giving itraconazole can produce adverse reactions if prescribed in combination with certain other drugs by increasing the concentrations of both drugs in the blood and creating a potentially life-threatening situation. Even **antacids** can significantly affect itraconazole levels. As a result, drug levels must be continually monitored to ensure that absorption is occurring at acceptable levels.

The antifungal drug posaconazole (Noxafil), has been approved by the United States Food and Drug Administration (FDA) to be given to as a preventative (prophylactic) to individuals with suppressed immune systems and at high risk of developing aspergillosis. The drug is given by daily injection, as a tablet, or as an oral suspension.

Prognosis

The likelihood of recovery from aspergillosis depends on any underlying medical conditions, the patient's general health, and the specific type of

KEY TERMS

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Aspergilloma—A ball or mass made of *Aspergillus* fungi that can form in the lungs of patients with suppressed immune systems.

Bronchial lavage—A procedure that involves repeatedly washing the inside of the bronchial tubes of the lung.

Hemoptysis—Spitting up blood from the lungs or sputum stained with blood.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

Meningitis—Inflammation of the membranes covering the brain and spinal cord, called the meninges.

Spores—The small, thick-walled reproductive structures of fungi.

Sputum—Mucus and other matter coughed up from the airways.

aspergillosis. If the problem is based on an allergic response, as in ABPA, the patient will likely respond well to systemic steroids.

Patients who require **lung surgery**, especially those who have problems with coughing up blood, have a mortality rate of about 7% to 14%, and complications or recurrence may result in a higher overall death rate. However, by treating aspergilloma with other, non surgical methods, that risk rises to 26%, making surgery a better option in some cases.

Unfortunately, the prognosis for the most serious form, invasive aspergillosis, is quite poor, largely because these patients have little resilience due to their underlying disorders. Death rates have ranged from about 50% in some studies to as high as 95% for bone-marrow recipients and patients with AIDS. The course of the illness can be rapid, resulting in death within a few months of diagnosis.

Prevention

At this point, daily drug treatment with posaconazole is the only preventative therapy for aspergillosis. This drug is only given to individuals at very high risk of developing the disease. Because exposure to the fungus is common in daily life, it is difficult to take preventive measures or reduce exposure. Seeking treatment if aspergillosis is suspected can ensure that treatment begins promptly and may help improve prognosis.

Aspirin

Definition

Aspirin is a medication given to relieve **pain** and reduce **fever**. The name *aspirin* was originally a trademark, first used when the drug was introduced in Europe in 1899. Aspirin was developed by a German chemist named Felix Hoffman as a treatment for his father's arthritis.

Purpose

Aspirin is used to relieve minor aches and pains—headaches, toothaches, muscle pain, menstrual cramps, joint pains associated with arthritis, and the general achiness that many people experience with colds and flu. Some people take aspirin daily to reduce the risk of **stroke**, **heart attack**, or other heart problems.

Description

Aspirin, also known as acetylsalicylic acid, is not a prescription drug. It is sold over the counter in many forms, from the familiar white tablets to chewing gum and rectal suppositories. Coated, chewable, buffered, and extended-release forms are available. Many other over-the-counter (OTC) medications contain aspirin. Alka-Seltzer Original Effervescent Antacid Pain Reliever (R), for example, contains aspirin for pain relief as well as **sodium** bicarbonate to relieve acid **indigestion**, **heartburn**, and sour stomach.

Aspirin belongs to a group of drugs called salicylates. Other members of this group include sodium salicylate, choline salicylate, and magnesium salicylate. These drugs are more expensive but generally no more effective than aspirin; however, they are preferred by some patients who find that aspirin upsets their stomach.

Aspirin is quickly absorbed into the bloodstream and provides rapid and relatively long-lasting pain relief. In high doses, aspirin also reduces inflammation. Researchers believe these effects are due to aspirin's ability to block the production of pain-producing chemicals called prostaglandins.

In addition to relieving pain and reducing inflammation, aspirin lowers fever by acting on the hypothalamus, which is the part of the brain that regulates temperature. The brain then signals the blood vessels to dilate (widen), which allows heat to leave the body more quickly.

KEY TERMS

Diuretic—A type of medication that increases the amount of urine produced and relieves excess fluid buildup in body tissues. Diuretics may be used in treating high blood pressure, lung disease, premenstrual syndrome, and other conditions.

Inflammation—A response to injury or illness characterized by pain, redness, swelling, and warmth.

Nonsteroidal anti-inflammatory drugs (NSAIDs)—Drugs that relieve pain and reduce inflammation but are not related chemically to cortisone. Common drugs in this class are aspirin, ibuprofen (Advil, Motrin), naproxen (Aleve, Naprosyn), and several others.

Polyp—Any mass of tissue that grows out of a mucous membrane in the digestive tract, uterus, or elsewhere in the body.

Prostaglandin—A hormone-like chemical produced in the body that has a variety of effects. Prostaglandins may be responsible for the production of some types of pain and inflammation.

Reye's syndrome—A life-threatening disease that affects the liver and the brain and sometimes occurs after a viral infection, such as flu or chickenpox. Children or teenagers who are given aspirin for flu or chickenpox are at increased risk of developing Reye's syndrome.

Rhinitis—Inflammation of the membranes inside the nose.

Salicylates—A group of drugs that includes aspirin and related compounds. Salicylates are used to relieve pain, reduce inflammation, and lower fever.

Stroke—An event that impairs the circulation of the brain. Ischemic stroke is caused by a blood clot in the brain. Hemorrhagic stroke is caused by bleeding into the brain.

Recommended dosage

Adults

PAIN OR FEVER. The usual dosage for pain relief or fever reduction is one to two 325 milligram (mg) tablets every three to four hours, up to six times per day or as directed by a physician.

STROKE. One baby aspirin (81 mg) tablet once a day to one standard (325 mg) tablet once a day is the typical recommended dose for stroke risk reduction, or as directed by a physician.

HEART ATTACK. Aspirin may be used as a first-line treatment for a heart attack. The patient should chew a single uncoated aspirin tablet, since chewing makes it easier for the body to absorb the medication rapidly. Aspirin will not stop a heart attack, and proper emergency care is essential; however, an aspirin tablet taken at the time of the heart attack may reduce the amount of damage done by the heart attack.

Patients should check with their physician for the proper dose and number of times per week they should take aspirin to reduce the risk of a heart attack. The most common dose for this purpose is a single baby aspirin tablet taken daily. Enteric-coated aspirin is often used, since it reduces the risk of stomach irritation.

Children

Parents should consult their child's physician about the proper dosage for their child's condition. If the child has a viral illness, **acetaminophen** (Tylenol) is generally preferred.

Precautions

Aspirin—even children's aspirin—should never be given to children or teenagers with flu-like symptoms or **chickenpox**. Aspirin can cause Reye's syndrome, a rare life-threatening condition that affects the nervous system and liver. As many as 30% of children and teenagers who develop Reye's syndrome die. Those who survive may have permanent brain damage.

Parents should consult a physician before giving aspirin to a child under 12 years of age for arthritis, rheumatism, or any condition that requires long-term use of the drug.

No one should take aspirin for more than ten days in a row unless instructed to do so by a physician. Anyone with fever should not take aspirin for more than three days without a physician's advice. In addition, no one should take more than the recommended daily dosage.

People in the following categories should not use aspirin without first checking with their physician:

- Pregnant women—aspirin can cause bleeding problems in both the mother and the developing fetus. Aspirin can also cause the infant's weight to be too low at birth.
- Women who are breast-feeding—aspirin can pass into breast milk and affect the baby.
- People with a history of bleeding/clotting problems.
- People who are taking such blood-thinning drugs as warfarin (Coumadin).
- People who have had recent surgery—aspirin increases the risk of bleeding from an incompletely healed incision.
- People with a history of stomach ulcers.
- People with a history of asthma, nasal polyps, or both; patients with these disorders are more likely to be allergic to aspirin.
- People who are allergic to fenoprofen, ibuprofen, indomethacin, ketoprofen, meclofenamate sodium, naproxen, sulindac, tolmetin, or an orange food coloring known as tartrazine; they may also be allergic to aspirin.
- People with AIDS or an HIV/AIDS-related complex who are taking zidovudine (AZT)—aspirin can increase the risk of bleeding in these patients.
- People taking any drugs known to interact with aspirin.
- People with liver damage or severe kidney failure.

Aspirin should not be taken before a surgical procedure or some dental procedures, as it can increase the risk of excessive bleeding. People scheduled for surgery should check with their surgeon to find out when they should discontinue taking aspirin.

Aspirin can cause stomach irritation. Taking aspirin with food or milk, or drinking an eight-ounce glass of water with it may help to prevent damage to the stomach lining. Some patients find that using coated or buffered aspirin reduces the risk of stomach upset. Patients should be aware, however, that drinking alcoholic beverages can make the stomach irritation worse.

Patients with any of the following symptoms should stop taking aspirin immediately and call their physician:

- a sensation of ringing or buzzing in the ears
- hearing loss
- dizziness
- stomach pain that does not go away

Patients should discard any aspirin that has developed a vinegary smell; it is a sign that the medication is too old and ineffective.

Side effects

The most common side effects of aspirin include upset stomach, heartburn, loss of appetite, and small amounts of blood in the stool. Less common side effects are **rashes**, **hives**, fever, vision problems, liver damage, thirst, stomach **ulcers**, and bleeding. People

WWW.BOOKBAZ.IR

with **asthma**, **rhinitis**, polyps in the nose, or **allergies** to aspirin may have trouble breathing after taking the drug.

Interactions

Aspirin may increase, decrease, or change the effects of many drugs. Aspirin can increase the toxicity of such drugs as methotrexate (Rheumatrex) and valproic acid (Depakote, Depakene). When taken with blood-thinning drugs such as warfarin (Coumadin) and dicumarol, aspirin can increase the risk of excessive bleeding. Aspirin counteracts the effects of certain other drugs, including angiotensin-converting enzyme (ACE) inhibitors and **beta blockers**, which lower blood pressure, and medicines used to treat **gout** (probenecid and sulfinpyrazone). Blood pressure may drop unexpectedly and cause **fainting** or **dizziness** if aspirin is taken along with nitroglycerin tablets. Aspirin may also interact with **diuretics**, diabetes medications, other **nonsteroidal anti-inflammatory drugs** (NSAIDs), seizure medications, and **steroids**. Anyone who is taking these drugs should ask his or her physician whether they can safely take aspirin.

Asthma

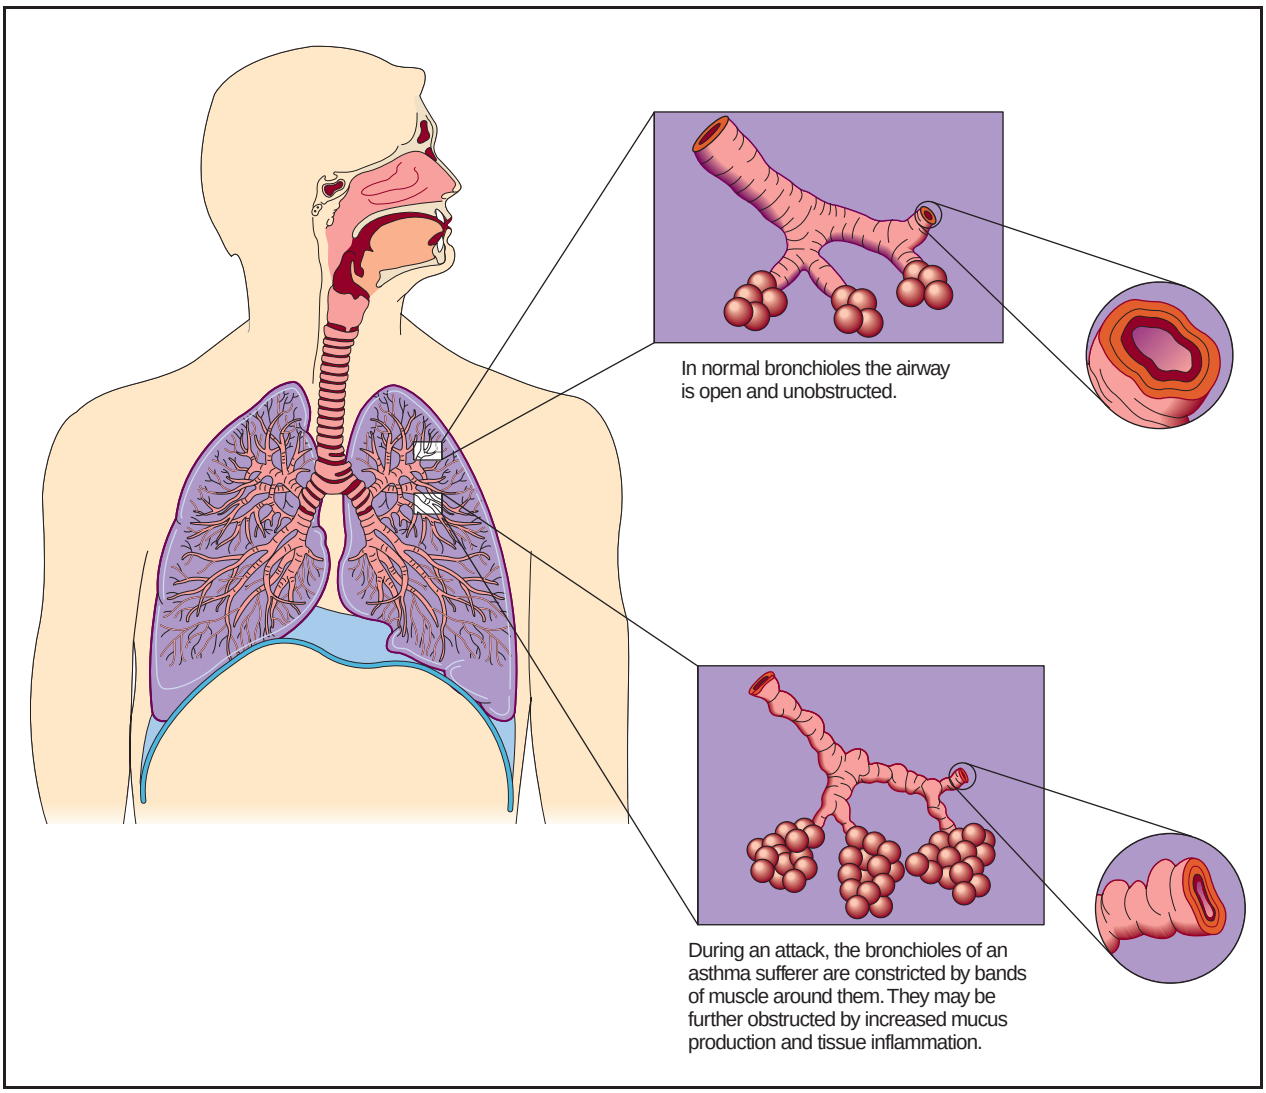
Definition

Asthma comprises a group of recurrent inflammatory diseases, in which the airways periodically spasm, swell, and narrow, causing **wheezing** or gasping for air. The majority of asthmas are associated with **allergies**.

Demographics

Asthma affects some 300 million people worldwide. In 2011, an estimated 25.9 million Americans had asthma, including 7.1 million children. In that year, 13.2 million Americans, including 4.1 million children, had asthma attacks. Although asthma can develop at any age, it usually first occurs during childhood, with the majority of children developing symptoms before the age of five. Asthma increased in the general population between 1990 and 2013, especially among young children, and the disease appeared to be becoming more severe. Asthma rates also increased dramatically among adolescents in industrialized countries between 1970 and 2013, especially among teens in urban environments. The global increase in asthma paralleled by similar increases in other allergic disorders, such as **eczema** and **allergic rhinitis**, and appeared to be associated with increased urbanization throughout the world.

The prevalence of asthma is higher among children from low-income families. African American children have an asthma rate that is about twice that of white American children; Puerto Ricans have twice the asthma rate as the overall Hispanic population; American Indians/Alaskan Natives have a rate that is 50% higher than Caucasians; Native Hawaiians/Pacific Islanders have 30% higher asthma rates than non-Hispanic whites. Although deaths from asthma are relatively rare, the death rate among Puerto Ricans is 400% higher than among non-Hispanic white



A comparison of normal bronchioles and those of a person with asthma. *(Illustration by Hans & Cassady, Inc. © Cengage Learning®.)*

Americans. African Americans also have higher death rates from asthma. However, the number and rate of hospitalizations for asthma decreased by 24%. There were 439,000 hospitalizations in 2010. This decline was believed to reflect improvements in controlling factors that prevent more severe attacks.

Description

Asthma causes changes in the airways—the bronchi and smaller bronchioles of the lungs—that make them hyper-reactive to many different types of stimuli that do not affect healthy lungs. In response to these triggers, mast cells in the bronchial walls release various immune-system chemicals, including histamine and leukotrienes. These chemicals stimulate mucus formation and cause the bronchial muscle to contract. They also recruit white blood cells to the area, initiating an inflammatory response. During an asthma attack, the muscle tissue in the walls of bronchi spasm, and the cells lining the airways swell and secrete mucus into the airways. Together, these activities cause the bronchi to narrow (bronchoconstriction), and inhalation and exhalation take much greater effort.

Allergic asthma is the most common form. It is caused by a sensitization reaction to a foreign substance called an allergen, such as pollen, household dust mites, mold, or animal dander. However, asthma also affects people who do not have allergies. Although airflow obstruction resolves spontaneously

WWW.BOOKBAZ.IR

or responds to treatment, continuing inflammation makes the airways hyper-responsive to stimuli such as cold air, **exercise**, and even **stress** and **anxiety**, as well as to allergens and air pollutants.

Child-onset asthma

Childhood asthma is most often caused by atopy, a genetic predisposition toward allergies in response to common environmental allergens and toward producing high levels of specific antibodies called immunoglobulin E (IgE) in response to those allergens. Once the airways become sensitized to a particular allergen, subsequent exposure can rapidly lead to an asthmatic response. Childhood asthma is often marked by asthmatic episodes followed by asthma-free periods, and many children outgrow asthma.

Adult-onset asthma

Adult-onset asthma differs from childhood asthma in various ways, although it may also involve allergies. Occupational asthma is caused by inhaling workplace plastics, solvents, wood dust, or other foreign substances. Other adults may be sensitive to various drugs, including **aspirin** and other **nonsteroidal anti-inflammatory drugs** (NSAIDs). Compared to childhood-onset asthma, adult-onset asthma tends to be ongoing. It is often severe and associated with loss of lung function.

Exercise-induced asthma (EIA)

Although exercise can trigger attacks in people with asthma, EIA can occur during or immediately after physical exertion in people who otherwise do not have asthma. Some estimates suggest that 12–15% of Americans without allergies are susceptible to EIA; rates of 40–90% have been reported for people who do have allergies. EIA episodes can last for several minutes and leave an individual gasping for breath. Inhaling cold air, aerobic exercise lasting more than 10 minutes, or shorter periods of very heavy aerobic exercise can trigger an attack in susceptible people. Polluted air and certain chemicals (for example, chlorine in swimming pools or herbicides on playing fields) appear to increase the risk for EIA.

Risk factors

The major risk factors for asthma are allergies or a family history of allergies or asthma. It is estimated that between one-third and one-half of the general population have atopy, and about 75% of people with asthma also have allergies. **Obesity** is also a risk factor for asthma.

Causes and symptoms

The development of asthma is strongly influenced by genetics. Variations in a number of different genes are known to increase susceptibility to asthma. In most cases, asthma is caused by inhaling an allergen to which the individual is hypersensitized. This sets off a chain reaction of biochemical and tissue changes leading to airway inflammation, bronchoconstriction, and wheezing. Asthma symptoms may be triggered or aggravated by **rhinitis** (inflammation of the lining of the nose, as from allergies) or **sinusitis** (sinus inflammation). In addition to inhaled allergens and exercise, inhaling cold air (cold-induced asthma), anxiety or stress, or even crying or laughing can invoke attacks in some people or may even be the only trigger for symptoms. Severe episodes often develop during a viral respiratory infection or exposure to a heavy load of an allergen or irritant, such as breathing in smoke from a campfire. Acid reflux (**heartburn**) can also worsen asthma symptoms. Aspirin and other NSAIDs and beta-blockers may worsen symptoms.

The most common inhaled allergens that trigger asthma attacks are:

- animal dander
- mites in household dust
- indoor mold
- cockroach allergens
- pollen
- chemicals, fumes, or airborne industrial pollutants
- wood or tobacco smoke

Wheezing and **shortness of breath** are usually the most obvious symptoms. Wheezing is often loudest during exhalation because of difficulty expelling air through narrowed airways. Coughing and/or a feeling of tightness in the chest are also common. Some people with asthma are symptom-free most of the time but have occasional episodes of shortness of breath. Others spend much of their time wheezing or have frequent bouts of shortness of breath. Asthma attacks may last only a few minutes or continue for hours or even days (a condition called status asthmaticus).

Shortness of breath from asthma may cause visible anxiety. The person may sit upright, lean forward, and use the neck and chest wall muscles to help move air in and out of the lungs. The person may be able to say only a few words before stopping to take a breath. During a severe attack that lasts for an extended period, some of the air sacs in the lung may rupture so that air collects within the chest, making it even

KEY TERMS

Allergen—A foreign substance, such as dust mites or animal dander, that causes an allergic reaction or hypersensitivity; in people with asthma, allergens can cause the airways to narrow and produce asthmatic symptoms.

Allergy—An abnormal or hypersensitive response by the immune system to an allergen, such as tissue inflammation and excess mucus production by the respiratory system.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Atopy—Genetic susceptibility to allergies and asthma.

Beta-agonist—Beta-adrenergic agonist; a drug the binds to beta receptors to cause adrenergic effects such as bronchodilation.

Bronchodilator—A drug that causes the expansion of the bronchial air passages.

Exercise-induced asthma (EIA)—Asthma attacks caused by aerobic exercise.

Histamine—An immune system chemical released by mast cells during an allergic reaction or asthma attack that has a variety of effects on other cells.

Immunoglobulin E (IgE)—Specific antibodies produced in the lungs, skin, and mucous membranes that are responsible for allergic reactions and asthma.

Inhaled corticosteroid (ICS)—An inhaled asthma medication.

Leukotriene—A chemical produced by immune system cells and lung tissue that is involved in allergic responses, including bronchoconstriction in asthma.

Leukotriene receptor antagonist (LTRA)—An asthma medication that controls airway inflammation by blocking the action of leukotrienes.

Long-acting beta-agonist (LABA)—An inhaled bronchodilator, often used in combination with a corticosteroid for asthma.

Mast cell—A type of immune system cell that displays immunoglobulin E (IgE) on its cell surface and participates in allergic reactions and asthma by releasing histamine and other chemicals from intracellular granules.

Metered-dose inhaler (MDI)—A device that delivers a measured dose of asthma medication directly into the lungs.

Nebulizer—A device for converting liquid asthma medication into a fine mist that can be inhaled directly into the lungs through a mouthpiece or facemask.

Nonsteroidal anti-inflammatory drugs (NSAIDs)—Over-the-counter and prescription medications for reducing inflammation and pain.

Spirometry—A test that measures breathing difficulty to determine asthma severity and response to treatment.

harder to breathe. Confusion and a bluish tint to the skin are indications of oxygen deprivation and a medical emergency.

Diagnosis

Examination

Asthma is commonly diagnosed from signs and symptoms, especially those that come on suddenly in response to specific stimulants, and a medical history of allergies or a family history of asthma. A mild asthma attack can be confirmed by listening for wheezing with a stethoscope. The physician will watch for maximum chest expansion when the patient inhales. Hunched shoulders and contracted neck muscles are other signs of narrowed airways.

Tests

Spirometry measures how rapidly air is exhaled and how much air is retained in the lungs. Spirometry that demonstrates the reversibility of bronchoconstriction with inhalation of a bronchodilating medication indicates asthma. Spirometry may be performed after exercise to diagnose EIA.

It is often difficult to determine the specific trigger(s) of asthma attacks. Allergy skin testing may be used, although a positive skin response does not necessarily mean that the tested allergen is responsible for the asthma. The immune system produces specific antibodies to each allergen, so measuring the amount of a specific antibody in the blood can indicate sensitivity to a particular allergen. Sometimes a suspected allergen is inhaled during spirometry to test for airway narrowing.

WWW.BOOKBAZ.IR

Procedures

A chest x ray may be performed to help rule out other lung disorders.

Treatment

Traditional

The goals of asthma treatment are to maintain lung function, prevent serious symptoms, and enable people to pursue normal activities, including those requiring exertion. Traditional treatment includes avoiding allergens and triggers, if possible, and managing asthmatic attacks when they occur. A severe asthma attack can be a medical emergency that requires supplemental oxygen and, rarely, mechanical ventilation.

Bronchial thermoplasty is a treatment for severe asthma, in which controlled radiofrequency energy reduces the smooth muscle tissue of the airway wall with heat. The smooth muscle is replaced by connective tissue, whereas other wall tissues regenerate normally. Bronchial thermoplasty has been shown to be safe and effective for at least five years.

Drugs

Asthma is often treated with a combination of long-acting drugs taken on a regular basis to help prevent attacks and short-acting (quick-relief) drugs administered with an inhaler to relieve immediate symptoms of an attack. The choice of initial drug treatment may depend on the asthma classification as intermittent, mildly persistent, moderately persistent, or severely persistent, as well as on the patient's age and any concurrent medical conditions and medications. It may take several attempts to find the best combination of drugs for controlling asthma. Once asthma has been controlled for several weeks or months, the dose may be reduced, usually beginning with the last drug added to the combination.

CORTICOSTEROIDS. Daily **inhaled corticosteroids** are the mainstay of treatment for mild-to-moderate asthma. **Corticosteroids**, which resemble natural body hormones, block inflammation and are often effective for relieving symptoms of chronic asthma and preventing attacks. Examples include fluticasone and beclomethasone. Over the long term, inhaled corticosteroids reduce the frequency of asthma attacks as the airways become less sensitive to allergens. However, poor adherence to daily medication remains an obstacle to prevention. Prednisone is taken orally to speed recovery after treatment of initial symptoms of an asthma attack and is sometimes used to treat chronic asthma. Corticosteroids can cause numerous side effects, especially over the long term, and can slow growth in children. Corticosteroids are not generally used to treat ongoing asthma attacks.

BETA-AGONISTS (BRONCHODILATORS). Beta-agonists, which relax the airways, are often the best choice for relieving sudden asthma attacks and for preventing EIA. Some **bronchodilators**, such as albuterol and levalbuterol, act primarily on lung cells and have little effect on other organs. Although occasionally taken orally as a pill or liquid, bronchodilators are normally inhaled directly into the lungs, where they act within minutes with few side effects. The effects last four to six hours. For a severe attack, a beta-agonist may be inhaled repeatedly or continuously. A corticosteroid may be added if the response is slow or incomplete, and a course of corticosteroid therapy may begin after the attack to reduce the likelihood of a recurrence. Side effects from beta-agonists (including racing heart and tremor) may be more common in older patients.

Long-acting beta-agonists (LABAs) last up to 12 hours and are used as additional therapy when low-dose inhaled corticosteroid (ICS) monotherapy does not control the asthma. Treatment is usually with a single inhaler containing an ICS/LABA combination, such as fluticasone for stronger, sustained anti-inflammatory effects and the LABA formoterol for rapid bronchodilation. Other combinations include budesonide/formoterol and fluticasone/salmeterol. Most inhalers powered by ozone-depleting chlorofluorocarbons (CFCs) were phased out in 2008 and replaced with inhalers powered by hydrofluoroalkanes. The remaining two CFC inhalers were withdrawn at the end of 2013.

OTHER DRUGS. Leukotriene-receptor antagonists (LTRAs), such as montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo), constitute a new class of drugs that control airway inflammation by blocking the action of inflammatory leukotrienes. They are oral tablets taken on a regular basis to prevent or treat symptoms of asthma and EIA. They have various potential side effects.

Various other drugs can be used to treat asthma:

- Cromolyn and nedocromil are inhaled anti-inflammatories that affect mast cells. They are used regularly, even in the absence of symptoms, to prevent asthma attacks and EIA.
- Anticholinergic drugs, such as atropine, may be useful in controlling severe attacks when added to an inhaled beta-agonist. They help widen airways and suppress mucus production.

- New biological therapies for severe asthma include antibodies against IgE and interleukins 5 and 13.

INFANTS AND CHILDREN. Asthma in infants and children must be carefully managed. Children often need medication at school to control acute symptoms or prevent EIA. Parents or guardians should consult with school personnel to assure that procedures are in place and that the school has the child's asthma treatment plan. Proper management usually enables a child to participate in normal school activities.

Most asthma medications are delivered through metered-dose inhalers (MDIs). Children often use a spacer with the MDI that holds the medication so that it can be inhaled in several breaths instead of one breath. The spacers may be fitted with a mask for young children. Nebulizers are devices that turn liquid asthma medications into inhaled mist. A 2013 study found that less than 20% of nebulizer medication reaches a child's lungs and that the inhaled amount depends on the drug formulation. Furthermore, only one out of 169 caregivers was familiar with all of the proper steps for assisting children with the devices. Researchers consider five of the ten steps to be essential for proper dose delivery:

- shaking the inhaler
- forming a seal between the child's face and the device
- pressing down (actuation) on the inhaler only once
- taking at least six deep slow breaths before a second actuation
- waiting at least 30 seconds after the six breaths before the second actuation

Alternatives

Alternative medicine tends to view asthma as the body's protective reaction to environmental agents and pollutants. Therefore, the treatment goal may be to restore balance and strength to the entire body and provide specific support to the lungs and immune and hormonal systems. Alternative treatments usually have minimal side effects and are generally inexpensive. They can be used alongside traditional drug treatments to improve their effectiveness and lessen negative side effects.

DIETARY AND NUTRITIONAL THERAPIES. Some alternative practitioners recommend reducing or eliminating dairy products in the diet, as these increase mucus secretion in the lungs and may be allergenic. Some studies have indicated that a sustained vegan diet can be effective for controlling asthma. Other recommendations include avoiding processed foods, refined starches and sugars, and foods with artificial additives and sulfites. **Diets** should be high in fresh fruits, vegetables, and whole grains and low in salt. People with asthma can experiment with their diets to determine whether **food allergies** are playing a role.

People with asthma should stay well-hydrated by drinking plenty of water to help keep airways moist. Onions and garlic contain quercetin, a flavonoid that inhibits the release of histamine. Quercetin is also available as a supplement and should be taken with a digestive enzyme to increase its absorption. Coffee and tea may reduce the severity of asthma attacks because **caffeine** is a bronchodilator. Tea also contains minute amounts of theophylline, a drug used to treat asthma.

A good multivitamin supplement or **vitamins** A, C, and E have been recommended for asthma. B complex vitamins, particularly B6 and B12, magnesium, selenium, and an omega-3 fatty-acid supplement such as flaxseed oil may be helpful.

In the late twentieth century, some researchers linked the increase in allergic asthma to dietary changes, including a decrease in dietary fiber. A 2013 study in mice found that those on a low-fiber diet had twice the number of allergic asthma-associated immune cells as those on a standard diet and that mice consuming easily fermentable fiber supplements had reduced numbers of asthma-specific immune cells. The fiber supplements increased gut bacteria that convert fiber into short-chain fatty acids. Adding short-chain fatty acids to drinking water reduced allergic lung inflammation in response to dust mites.

HERBAL REMEDIES. Various Chinese medicine formulas are used to prevent or ease asthma attacks. **Traditional Chinese medicine** treats asthma attacks with *ma huang*. However, *ma huang* contains ephedrine, a bronchodilator that is banned in the United States because it can raise blood pressure and stress the circulatory system, sometimes leading to heart attacks or strokes. Gingko has been suggested to reduce the frequency of asthma attacks, and licorice is used in traditional Chinese medicine as a natural decongestant and expectorant. Ayurvedic (traditional East Indian) medicine recommends the herb *Tylophora asthmatica*.

Other herbs used for asthma are:

- lobelia
- nettle, which contains a natural antihistamine
- thyme
- mullein
- feverfew
- passionflower
- saw palmetto
- Asian ginseng

WWW.BOOKBAZ.IR

MIND/BODY APPROACHES. Mind/body medicine has demonstrated that psychological factors may play a complex role in asthma. **Biofeedback**, relaxation and deep breathing methods, **meditation**, and other stress-reducing techniques, **hypnotherapy**, mental imaging, **psychotherapy**, or visualization can help address psychological components of asthma. Some studies have shown that **yoga** can significantly affect asthma by teaching lung expansion and deep breathing and by reducing stress. Pranayama is the yogic science of breathing, which includes hundreds of deep-breathing techniques. These breathing exercises can be an effective and inexpensive part of a daily asthma treatment program.

CONTROLLED EXERCISE. Studies have shown that many children with asthma do not get enough exercise. Physical exercise is important, and parents should work with their children's healthcare providers and sports leaders to carefully monitor their activities.

ACUPUNCTURE AND ACUPRESSURE. Acupuncture is used along with dietary changes in traditional Chinese medicine. **Acupressure** can be used as self-treatment for asthma attacks and prevention. The Lung 1 points, used to stimulate breathing, are readily found on the chest. They are sensitive, often knotted spots on the muscles that run horizontally about an inch below the collarbone and about two inches from the center of the chest. The points are pressed in a circular manner with the thumbs, while the head hangs forward during slow, deep breathing. **Reflexology** uses particular acupressure points on the hands and feet to stimulate the lungs.

OTHER TREATMENTS. Other alternative therapies include the following:

- aromatherapy with eucalyptus, lavender, rosemary, or chamomile to promote free breathing
- hydrotherapy to open constricted air passages
- massage therapies such as Rolfing that open and increase circulation in the chest area
- the homeopathic remedies *Arsenicum album*, *Kali carbonicum*, *Natrum sulphuricum*, and *Aconite*

Home remedies

At-home monitoring is a very important component of asthma management. A diary of asthma attacks can help identify allergens and environmental and emotional triggers. School-age children and adults can track their asthma severity with a peak-flow meter—a simple devices that measures ease of exhalation. Home peak-flow monitoring makes it possible for many people to recognize the start of a flare-up and adjust medications accordingly.

Personalized asthma action plans are instructions to be followed when symptoms increase or peak flow begins to decrease. School asthma action plans and plans for adolescents and adults are available from the Asthma and Allergy Foundation. Peak expiratory flow rates are divided into colored zones for deciding on treatment.

- Green indicates satisfactory lung function and the continuation of regular medications and activities as long as symptoms are absent or well-controlled.
- Yellow indicates narrowing of the airways and increased severity or frequency of symptoms that usually require a short-term change or increase in medication according to one's personal action plan.
- Red indicates severe narrowing of the airways with more severe and more frequent symptoms that require immediate treatment, such as two to four puffs of a quick-acting inhaler, such as albuterol, or steroid tablets.
- A personal emergency-care plan may include more frequent use of a reliever such as albuterol or initiating or increasing the dosage of a long-term controller such as prednisone. If symptoms fail to improve or worsen, emergency medical assistance should be summoned.

Prognosis

More than half of all childhood asthmas resolve by young adulthood, although chronic infections or chronic exposure to allergens, pollution, or cigarette smoke make resolution less likely. Infants and toddlers with persistent wheezing or with a family history of allergies are most likely to have asthma continue into their school years. Asthma usually responds well once the proper drug or drug combination is determined, and most people are able to lead relatively normal, active lives. Sometimes asthma progressively worsens, eventually leading to **respiratory failure** and 3,500–5,000 deaths annually n the United States.

Prevention

There is no proven strategy for preventing asthma, although early exposure to microbes, especially from indoor/outdoor pets and livestock, appears to be somewhat protective by altering the balance of microbes in the human gut and respiratory system. Some studies suggest that high maternal intake of fish during **pregnancy** may protect infants and children from asthma.

There are various measures for reducing or eliminating exposure to common allergens and irritants that provoke asthma attacks:

- avoiding pets, keeping pets away from bedrooms and upholstered furniture, and removing carpeting
- using special covers for pillows and mattresses, minimizing stuffed toys, and washing them weekly in hot water to reduce exposure to dust mites
- killing cockroaches with poisons, traps, or boric acid rather than sprayed pesticides and covering food and garbage to discourage reinfestation
- keeping indoor air clean by vacuuming carpets once or twice a week when the person with asthma is away, avoiding humidifiers, using air conditioners to keep windows closed, changing heating and air-conditioning filters regularly, and using high-efficiency particulate air (HEPA) filters to remove allergens
- avoiding exposure to tobacco and wood smoke
- avoiding outdoor exercise in the cold and when air pollution levels are high
- wearing a mask and, if necessary, arranging to work in a safer area to avoid occupational asthma

Astigmatism can be treated by the use of cylindrical lenses. The lenses are shaped to counteract the shape of the sections of the cornea that are causing the difficulty. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Astigmatism

Definition

Astigmatism is the result of an inability of the cornea to properly focus an image onto the retina. The result is a blurred image.

Description

The cornea is the outermost part of the eye. It is a transparent layer that covers the colored part of the eye (iris), pupil, and lens. The cornea bends light and helps to focus it onto the retina where specialized cells (photo receptors) detect light and transmit nerve impulses via the optic nerve to the brain where the image is formed. The cornea is dome shaped. Any incorrect shaping of the cornea results in an incorrect focusing of the light that passes through that part of the cornea. The bending of light is called refraction and focusing problems with the cornea are called diseases of refraction or refractive disorders. Astigmatism is an image distortion that results from an improperly shaped cornea. Usually the cornea is spherically shaped, like a baseball. However, in astigmatism the cornea is elliptically shaped, more like a football. There is a long meridian and a short meridian. These two meridians generally have a constant curvature and are generally perpendicular to each other (regular astigmatism). Irregular astigmatism may have more than two meridians of focus and they may not be 90° apart. A point of light, therefore, going through an astigmatic cornea will have two points of focus, instead of one nice sharp image on

KEY TERMS

Meridian—A section of a sphere. For example, longitude or latitude on the globe. Or, on a clock, a section going through 12:00-6:00 or 3:00-9:00.

Refraction—The turning or bending of light waves as the light passes from one medium or layer to another. In the eye it means the ability of the eye to bend light so that an image is focused onto the retina.

the retina. This will cause the person to have blurry vision. What the blur looks like will depend upon the amount and the direction of the astigmatism. A person with nearsightedness (**myopia**) or farsightedness (**hyperopia**) may see a dot as a blurred circle. A person with astigmatism may see the same dot as a blurred oval or frankfurter-shaped blur.

Some cases of astigmatism are caused by problems in the lens of the eye. Minor variations in the curvature of the lens can produce minor degrees of astigmatism (lenticular astigmatism). In these patients, the cornea is usually normal in shape. Infants, as a group, have the least amount of astigmatism. Astigmatism may increase during childhood, as the eye is developing.

Causes and symptoms

The main symptom of astigmatism is blurring. People can also experience headaches and eyestrain. Parents can notice that a child may have astigmatism when the child can see some part of a pattern or picture more clearly than others. For example, lines going across may seem clearer than lines going up and down.

Regular astigmatism can be caused by the weight of the upper eyelid resting on the eyeball creating distortion, surgical incisions in the cornea, **trauma** or scarring to the cornea, the presence of tumors in the eyelid, or a developmental factor. Irregular astigmatism can be caused by scarring or keratoconus. Keratoconus is a condition in which the cornea thins and becomes cone shaped. It usually occurs around **puberty** and is more common in women. Although the causes of keratoconus are unknown, it may be hereditary or a result of chronic eye rubbing, as in people with **allergies**. The center of the cone may not be in line with the center of the cornea. Diabetes can play a role in the development of astigmatism. High blood sugar levels can cause shape changes in the lens of the eye. This process usually occurs slowly and, often, is only noticed when the diabetic has started treatment to control their blood sugar. The return to a more normal blood sugar allows the lens to return to normal and this change is sometimes noticed by the patient as farsightedness. Because of this, diabetics should wait until their blood sugar is under control for at least one month to allow vision to stabilize before being measured for eyeglasses.

Diagnosis

Patients seek treatment because of blurred vision. A variety of tests can be used to detect astigmatism during the eye exam. The patient may be asked to describe the astigmatic dial, a series of lines that radiate outward from a center. People with astigmatism will see some of the lines more clearly than others. One diagnostic instrument used is the keratometer. This measures the curvature of the central cornea. It measures the amount and direction of the curvature. A corneal topographer can measure a larger area of the cornea. It can measure the central area and mid-periphery of the cornea. A keratoscope projects a series of concentric light rings onto the cornea. Misshapen areas of the cornea are revealed by noting areas of the light pattern that do not appear concentric on the cornea. Because these instruments are measuring the cornea, it is also important to have a refraction in case the lens is also contributing to the astigmatism. The refraction measures the optics or visual status of the eye and the result is the eyeglass prescription. The refraction is when the patient is looking at an eye chart and the doctor is putting different lenses in front of the patient's eyes and asks which one looks better.

Treatment

Astigmatism can be treated by the use of cylindrical lenses. They can be in eyeglasses or **contact lenses**. The unit of measure describing the power of the lens system or lens is called the diopter (D). The lenses are shaped to counteract the shape of the sections of cornea that are causing the difficulty. Because the correction is in one direction, it is written in terms of the axis the correction is in. On a prescription, for example, it may say $-1.00 \times 180°$. Cylinders correct astigmatism, minus spheres correct myopia, and plus spheres correct hyperopia.

WWW.BOOKBAZ.IR

There is some debate as to whether people with very small amounts of astigmatism should be treated. Generally, if visual acuity is good and the patient experiences no overt symptoms, treatment is not necessary. When treating larger amounts of astigmatism, or astigmatism for the first time, the doctor may not totally correct the astigmatism. The cylindrical correction in the eyeglasses may make the floor appear to tilt, thus making it difficult for the patient at first. Generally, the doctor will place lenses in a trial frame to allow the patient to try the prescription at the exam. It may take a week or so to get used to the glasses, however; if the patient is having a problem they should contact their doctor, who might want to recheck the prescription.

Contact lenses that are used to correct astigmatism are called toric lenses. When a person blinks, the contact lens rotates. In toric lenses, it is important for the lens to return to the same position each time. Lenses have thin zones, or cut-off areas (truncated), or have other ways to rotate and return to the correct position. Soft toric lenses are available in a variety of prescriptions, materials, and even in tints. Patients should ask their doctors about the possibility of toric lenses.

In 1997, the Food and Drug Administration (FDA) approved laser treatment of astigmatism. Patients considering this should make sure the surgeon has a lot of experience in the procedure and discuss the possible side effects or risks with the doctor. In the case of keratoconus, a corneal transplant is performed if the astigmatism cannot be corrected with hard contact lenses.

Prognosis

Astigmatism is a condition that may be present at birth. It may also be acquired if something is distorting the cornea. Vision can generally be corrected with eyeglasses or contact lenses. The major risks of surgery (aside from the surgical risks) are over and under correction of the astigmatism. There is no cure for over correction. Under correction can be solved by repeating the operation.

Aston-Patterning

Definition

Aston-Patterning is an integrated system of movement education, bodywork, ergonomic adjustments, and fitness training that recognizes the relationship between the body and mind for well being. It helps people who seek a remedy from acute or chronic **pain** by teaching them to improve postural and movement patterns.

Purpose

Aston-Patterning assists people in finding more efficient and less stressful ways of performing the simple movements of everyday life to dissipate tension in the body. This is done through massage, alteration of the environment, and fitness training.

Description

Seeking to solve movement problems, Aston-Patterning helps individuals make the most of their own unique body types rather than trying to force them to conform to an ideal. Unlike **Rolfing**, it does not strive for linear symmetry. Rather, it works with asymmetry in the human body to develop patterns of alignment and movement that feel right to the individual. Aston introduced the idea of working in a three-dimensional spinal pattern. Aston-Patterning sessions have four general components:

- a personal history that helps the practitioner assess the client's needs
- pre-testing, in which the practitioner and the client explore patterns of movement and potential for improvement
- movement education and bodywork, including massage, myofacial release, and arthrokinetics to help release tension and make new movement patterns easier
- post-testing, when pre-testing movements are repeated, allowing the client to feel the changes that have taken place and integrate them into daily life

Aston-Patterning requires more participation from the client than many bodywork techniques. The massage aspect of Aston-Patterning is designed around a three-dimensional, non-compressive touch that releases patterns of tension in the body. It is gentler than Rolfing. Myokinetics uses touch to release tension in the face and neck. Arthrokinetics addresses tension at bones and joints. This massage

JUDITH ASTON

Judith Aston was born in Long Beach, California. She graduated from University of California at Los Angeles with a B.A. and a M.F.A. in dance. Her interest in movement arose from working as a dancer. In 1963 Aston established her first movement education program for dancers, actors, and athletes at Long Beach City College.

Five years later, while recovering from injuries sustained during two consecutive automobile accidents, Aston met Ida Rolf, the developer of Rolfing. Aston began working for Rolf, teaching a movement education program called Rolf-Aston Structural Patterning, which emphasized using the body with minimum effort and maximum precision.

In time, Rolf and Aston's views on movement diverged, and the partnership was dissolved in 1977. Aston formed her own company called the Aston Paradigm Corporation in Lake Tahoe, California. This company provides training and certification for Aston practitioners. She also began exploring how environmental conditions affect body movement, foreshadowing the ergonomic movement in the workplace that developed in the 1990s. Over time, Aston expanded her movement work to include a fitness program for older adults. As of 2014, Judith Aston served as director of Aston Paradigm Corporation. She is the author of the books *Moving Beyond Posture—In Your Body on the Earth*, the *Aston Postural Assessment Workbook*, and the DVD *Aston's Walking the New Body*. More information on her work can be found at http://www.astonkinetics.com/

is accompanied by education about how new movement patterns may be established.

In addition to Aston-Patterning sessions, clients are helped to examine their environment for factors, such as seating or sleeping arrangements, that may limit their body function and introduce tension. Finally, they may choose to participate in the Aston fitness training program that includes loosening techniques based on self-massage, toning, stretching, and cardiovascular fitness.

Preparations

No special preparation need be taken.

Precautions

No special precautions are necessary when participating.

Side effects

No undesirable side effects are reported. Usually, clients report a diminution of tension, improved body movement, and an enhanced feeling of well being.

Research and general acceptance

Aston-Patterning is an outgrowth of Rolfing, which has been shown to be of benefit in a limited number of controlled studies. Little controlled research has been done on the either benefits or limitations of Aston-Patterning. Its claims have been neither proven nor disproven, although anecdotally many clients report relief from pain and tension and improved body movement.

KEY TERMS

Rolfing—Developed by Dr. Ida Rolf (1896–1979); a systematic approach to relieving stress patterns and dysfunctions in the body's structure through the manipulation of the highly pliant myofacial (connective) tissue. It assists the body in reorganizing its major segments into vertical alignment.

Ataxia-telangiectasia

Definition

Ataxia-telangiectasia (A-T), also called Louis-Bar syndrome, is a rare, genetic neurological disorder of childhood that progressively destroys part of the motor control area of the brain, leading to a lack of balance and coordination. A-T also affects the immune system and increases the risk of leukemia and lymphoma in affected individuals.

Description

The disorder first appeared in the medical literature in the mid-1920s, but was not named specifically until 1957. The name is a combination of two recognized abnormalities: ataxia (lack of muscle control) and telangiectasia (abnormal dilatation of capillary vessels that often result in tumors and red **skin lesions**). However, A-T involves more than just the sum of these two findings. Other associated A-T problems include immune system deficiencies, extreme sensitivity to radiation, and blood cancers.

Medical researchers initially suspected that multiple genes (the units responsible for inherited features) were involved. However, in 1995, mutations in a single large gene were identified as causing A-T. Researchers named the gene ATM for A-T, mutated. Subsequent research revealed that ATM has a significant role in regulating cell division. The symptoms associated with A-T reflect the main role of the AT gene, which is to induce several cellular responses to DNA damage, such as preventing damaged DNA from being reproduced. When the AT gene is mutated into ATM, the signaling networks are affected and the cell no longer responds correctly to minimize the damage.

A-T is very rare, but it occurs in every population world wide, with an estimated frequency of between 1/40,000 and 1/100,000 live births. But it is believed that many A-T cases, particularly those who die at a young age, are never properly diagnosed. Therefore, this disease may actually be much more prevalent. According to the A-T Project Foundation, an estimated 1% (2.5 million in the United States) of the general population carries defective A-T genes. Carriers of one copy of this gene do not develop A-T, but have a significantly increased risk of cancer. This makes the A-T gene one of the most important cancer-related genes identified to date.

Causes and symptoms

The ATM gene is autosomal recessive, meaning the disease occurs only if a defective gene is inherited from both parents. Infants with A-T initially often appear very healthy. At around age two, ataxia and nervous system abnormalities becomes apparent. The root cause of A-T-associated ataxia is cell death in the brain, specifically the large branching cells of the nervous system (Purkinje's cells) which are located in the cerebellum. A toddler becomes clumsy, loses balance easily and lacks muscle control. Speech becomes slurred and more difficult, and the symptoms progressively worsen. Between ages two and eight, telangiectases, or tiny, red "spider" veins, appear on the cheeks and ears and in the eyes.

By age 10–12, children with A-T can no longer control their muscles. Immune system deficiencies become common, and affected individuals are extremely sensitive to radiation. Immune system deficiencies vary between individuals but include lower-than-normal levels of proteins that function as antibodies (immunoglobulins) and white blood cells (blood cells not containing "iron" proteins). The thymus gland, which aids in development of the body's immune system, is either missing or has developed abnormally. Intelligence is normal, but growth may be retarded owing to immune system or hormonal deficiencies. Individuals with A-T are also sometimes afflicted with diabetes, prematurely graying hair, and difficulty swallowing. As the children grow older, the immune system becomes weaker and less capable of fighting infection. In the later stages, recurrent respiratory infections and blood cancers, such as leukemia or lymphoma, are common.

KEY TERMS

Angioma—A tumor (such as a hemangioma or lymphangioma) that mainly consists of blood vessels or lymphatic vessels.

Antibody—Any of a large number of proteins produced by specialized blood cells after stimulation by an antigen and that act specifically against the antigen in an immune response.

Antigen—Any substance (such as a toxin or enzyme) capable of stimulating an immune response in the body.

Ataxia—The inability to control voluntary muscle movement, most frequently resulting from disorders in the brain or spinal cord.

Autosomal—Relating to any of the chromosomes except for X and Y, the sex chromosomes.

Cerebellum—The part of the brain responsible for coordination of voluntary movements.

Gamma-globulin—An extract of human blood that contains antibodies.

Immune response—A response from the body to an antigen that occurs when the antigen is identified as foreign and that induces the production of antibodies and lymphocytes capable of destroying the antigen or making it harmless.

Immunoglobulin—A protein in the blood that is the component part of an antibody.

Leukemia—A cancer of blood cells characterized by the abnormal increase in the number of white blood cells in the tissues. There are many types of leukemias and they are classified according to the type of white blood cell involved.

Lymphoma—A blood cancer in which lymphocytes, a variety of white blood cells, grow at an unusually rapid rate.

Mutation—Any change in the hereditary material of genes.

Purkinje's cells—Large branching cells of the nervous system.

Recessive—Producing little or no phenotypic effect when occurring in heterozygous condition with a contrasting allele.

Telangiectases—Spidery red skin lesions caused by dilated blood vessels.

Telangiectasia—Abnormal dilation of capillary blood vessels leading to the formation of telangiectases or angiomas.

Thymus—A gland located in the front of the neck that coordinates the development of the immune system.

Diagnosis

Diagnosis relies on recognizing the hallmarks of A-T: progressive ataxia and telangiectasia. However, this may be difficult as ataxia symptoms do appear prior to telangiectasia symptoms by several years. Other symptoms can vary between individuals; for example, 70% of individuals with A-T have a high incidence of respiratory infection, 30% do not. The identification of the ATM gene raises hopes that screening, and perhaps treatment, may be possible.

Treatment

There is no cure for A-T, and treatment focuses on managing the individual's multiple symptoms. **Physical therapy** and **speech therapy** can help the patient adjust to ataxia. Injections of **gamma globulin**, or extracts of human blood that contain antibodies, are used to strengthen the weakened immune system. High-dose vitamin administrations may also be prescribed. Research continues in many countries to find effective treatments. Individuals and families living with this disorder may benefit from attending support groups.

Prognosis

A-T is a fatal condition. Children with A-T become physically disabled by their early teens and typically die by their early 20s, usually from the associated blood cancers and malignancies. In very rare cases, individuals with A-T may experience slower progression and a slightly longer life span, surviving into their 30s. A-T carriers have a five-fold higher risk than non-carriers of developing certain cancers, especially **breast cancer**.

Prevention

Medical researchers are investigating methods for screening individuals who may be carriers of the defective gene. Prenatal testing for A-T is possible but not done routinely, because commercial screening tests have yet to be developed.

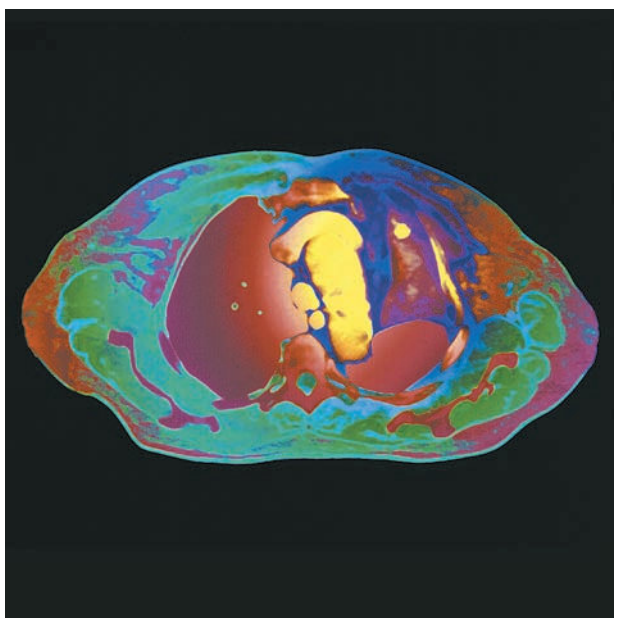
Atelectasis

Definition

Atelectasis is a collapse of lung tissue affecting part or all of one lung. This condition prevents normal oxygen absoption to healthy tissues.

Description

Atelectasis can result from an obstruction (blockage) of the airways that affects tiny air sacs called alveoli. Alveoli are very thin-walled and contain a rich blood supply. They are important for lung function, since their purpose is the exchange of oxygen and carbon dioxide. When the airways are blocked by a mucous "plug," foreign object, or tumor, the alveoli are unable to fill with air and collapse of lung tissue can occur in the affected area. Atelectasis is a potential complication following surgery, especially in individuals who have undergone chest or abdominal operations resulting in associated abdominal or chest **pain** during breathing. Congenital atelectasis can result from a failure of the lungs to expand at birth. This congenital condition may be localized or may affect all of both lungs.



A computed tomography (CT) scan through a patient's chest. The collapsed lung appears at the right of the image. *(Photo Researchers, Inc.)*

Causes and symptoms

Causes of atelectasis include insufficient attemps at respiration by the newborn, bronchial obstruction, or absence of surfactant (a substance secreted by alveoli that maintains the stability of lung tissue by reducing the surface tension of fluids that coat the lung). This lack of surfactant reduces the surface area available for effective gas exchange causing it to collapse if severe. Pressure on the lung from fluid or air can cause atelectasis as well as obstruction of lung air passages by thick mucus resulting from various infections and lung diseases. Tumors and inhaled objects can also cause obstruction of the airway, leading to atelectasis.

Anyone undergoing chest or abdominal surgery using general **anesthesia** is at risk to develop atelectasis, since breathing is often shallow after surgery to avoid pain from the surgical incision. Any significant decrease in airflow to the alveoli contributes to pooling of secretions, which in turn can cause infection. Chest injuries causing shallow breathing, including fractured ribs, can cause atelectasis. Common symptoms of atelectasis include **shortness of breath** and decreased chest wall expansion. If atelectasis only affects a small area of the lung, symptoms are usually minimal. If the condition affects a large area of the lung and develops quickly, the individual may turn blue (cyanotic) or pale, have extreme shortness of breath, and feel a stabbing pain on the affected side. **Fever** and increased heart rate may be present if infection accompanies atelectasis.

Diagnosis

To diagnose atelectasis, a doctor starts by recording the patient's symptoms and performing a thorough **physical examination**. When the doctor listens to the lungs through a stethoscope (ausculation), diminished or bronchial breath sounds may be heard. By tapping on the chest (percussion) while listening through the stethoscope, the doctor can often tell if the lung is collapsed. A chest x ray that shows an airless area in the lung confirms the diagnosis of atelectasis. If an obstruction of the airways is suspected, a computed

KEY TERMS

Alveoli—Tiny air sacs in the lungs where gas exchange takes place between alveolar air and pulmonary blood within the capillaries

Bronchial—Relating to the air passages to and from the lungs including the bronchi and the bronchioles.

Bronchoscopy—A procedure in which a hollow, flexible tube is inserted into the airway to allow visual examination of the larynx, trachea, bronchi, and bronchioles. It is also used to collect specimens for biopsy or culturing and to remove airway obstructions.

Incentive spirometer—A breathing device that provides feedback on performance to encourage deep breathing.

Mucus—A thin, slippery film secreted by the mucous membranes and glands.

Postural drainage—Techniques to help expel excess mucus by specific positions of the body (that decrease the effects of gravity) combined with manual percussion and vibration over various parts of the lung.

Surfactant—A substance secreted by the alveoli in the lungs that reduces the surface tension of lung fluids, allowing gas exchange and helping maintain the elasticity of lung tissue.

Tumor—An abnormal growth of tissue resulting from uncontrolled, progressive multiplication of cells.

tomography scan (CT) or **bronchoscopy** may be performed to locate the cause of the blockage.

Treatment

If atelectasis is due to obstruction of the airway, the first step in treatment is to remove the cause of the blockage. This may be done by coughing, suctioning, or bronchoscopy. If a tumor is the cause of atelectasis, surgery may be necessary to remove it. **Antibiotics** are commonly used to fight the infection that often accompanies atelectasis. In cases where recurrent or long-lasting infection is disabling or where significant bleeding occurs, the affected section of the lung may be surgically removed.

Prognosis

If atelectasis is caused by a thick mucus plug or inhaled foreign object, the patient usually recovers completely when the blockage is removed. If it is caused by a tumor, the outcome depends on the nature of the tumor involved. If atelectasis is a result of surgery, other post-operative conditions and/or complications affect the prognosis.

Prevention

When recovering from surgery, frequent repositioning in bed along with coughing and deep breathing are important. Coughing and breathing deeply every one to two hours after any surgical operation with general anesthesia is recommended. Breathing exercises and the use of breathing devices, such as an incentive spirometer, may also help prevent atelectasis. Although smokers have a higher risk of developing atelectasis following surgery, stopping **smoking** six to eight weeks before surgery can help reduce the risk. Increasing fluid intake during respiratory illness or after surgery (by mouth or intravenously) helps lung secretions to remain loose. Increasing humidity may also be beneficial.

Postural drainage techniques can be learned from a respiratory therapist or physical therapist and are a useful tool for anyone affected with a respiratiory illness that could cause atelectasis. Because **foreign objects** blocking the airway can cause atelectasis, it is very important to keep small objects that might be inhaled away from young children.

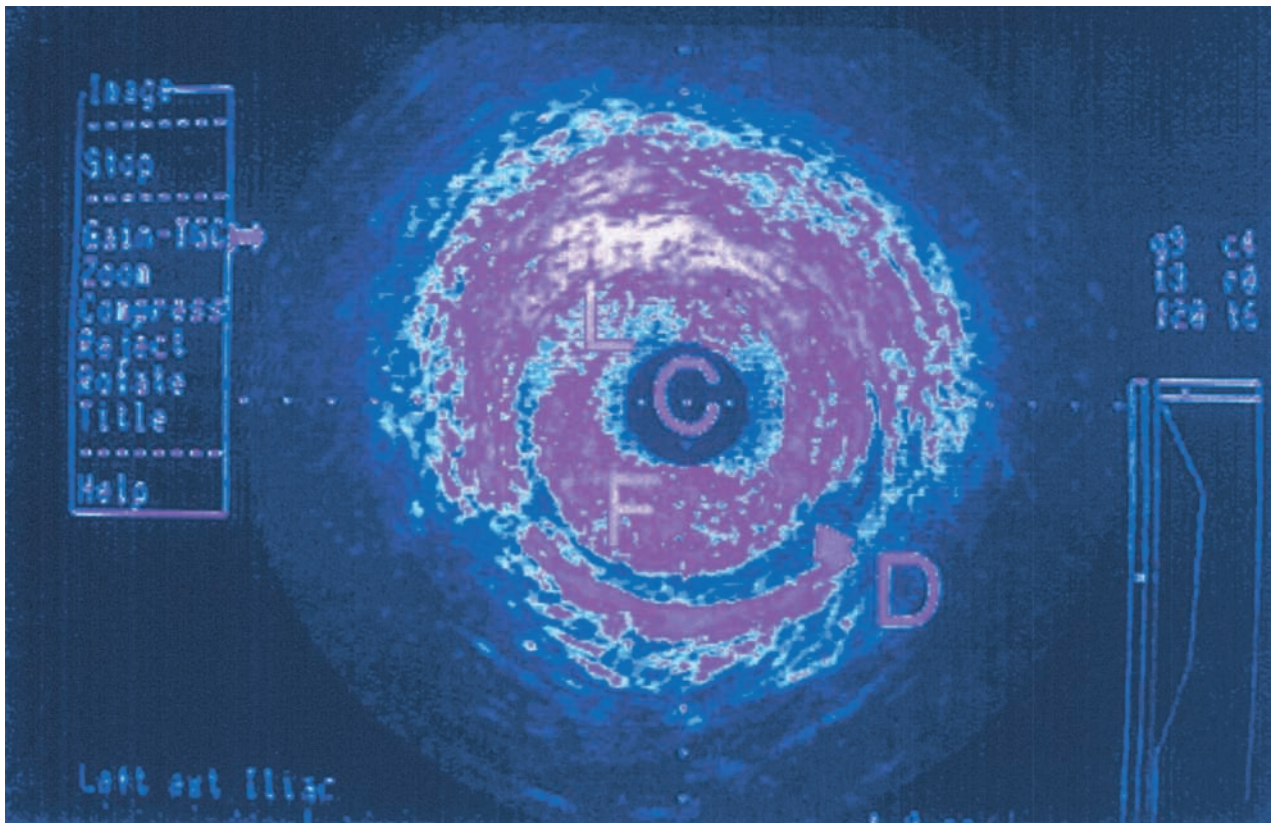
Atherectomy

Definition

Atherectomy is a procedure to open blocked arteries or vein grafts by using a device on the end of a catheter to cut or shave away atherosclerotic plaque blocking the flow of blood.

WWW.BOOKBAZ.IR



In this digitized ultrasound of a blood vessel, C is the catheter, D is the dissection, and F is the artherosclerotic flap. *(Custom Medical Stock Photo, Inc.)*

Purpose

Atherectomy is performed on the coronary arteries to restore the flow of oxygen-rich blood to the heart, to relieve chest **pain**, and to prevent heart attacks. It may be done on patients with chest pain who have not responded to other medical therapy and on some individuals who are candidates for balloon **angioplasty** or **coronary artery bypass graft surgery**. It is sometimes performed to remove plaque that has built up after a coronary artery bypass graft surgery. Artherectomy may also be performed on the carotid arteries leading to the brain or on certain vertebral arteries.

Description

Atherectomy uses a catheter inserted into the artery that has at its tip either a rotating device that reams out the artery, a device that shaves the plaque away, or a laser that vaporizes the plaque. At the beginning of the procedure, medications are administered to control blood pressure, dilate the coronary arteries, and prevent **blood clots**. The patient is awake but sedated. The catheter is inserted into an artery in the groin, leg, or arm, and threaded through the blood vessels into the blocked artery. The cutting head or laser is positioned against the plaque and activated, and the plaque is ground up and suctioned out or vaporized.

In some patients, artherectomy can be an alternative to coronary bypass surgery. It is significantly less painful, less costly, and has a much shorter recovery time than bypass surgery. The location(s), degree of blockage, and general health status of the individual are all factors in deciding whether artherectomy is the most appropriate procedure.

The types of atherectomy are directional, rotational, transluminal extraction and laser artherectomy extraction. Directional atherectomy was the first type approved, but is no longer commonly used; it scrapes plaque into an opening in one side of the catheter. Rotational atherectomy uses a high-speed rotating shaver to grind up plaque. Transluminal extraction uses a device that cuts plaque off vessel walls and vacuums it into a bottle. It is used to clear bypass grafts. Laser artherectomy uses a laser to break up

KEY TERMS

Atherosclerotic plaque—A deposit of fat and other substances that accumulate in the lining of the artery wall.

Balloon angioplasty—A surgical procedure in which a balloon catheter is used to flatten plaque against an artery wall.

Carotid artery—An artery located in the neck.

Catheter—A long, thin, flexible tube that can be inserted into a vein and moved through the cardiovascular system.

Coronary arteries—These are the first arteries to branch off the aorta (the large artery leaving the heart). The coronary arteries surround the heart like a crown, coming out of the aorta, arching down over the top of the heart, dividing into two branches, and taking oxygen-rich blood to the heart muscle. Blockage of these arteries can cause atherosclerosis and heart attack.

Electrocardiogram (ECG, EKG)—A test that records the electrical activity of the heart using small electrode patches attached to the skin on the chest.

Plaque—Fatty material that is deposited on the inside of the arterial wall.

Stent—A device made of expandable, metal mesh that is placed (by using a balloon catheter) at the site of a narrowing artery; the stent stays in place to keep the artery open.

and vaporize the plaque. In some patients, a balloon angioplasty may be done and a stent inserted after successful artherectomy.

Performed in a **cardiac catheterization** lab, atherectomy can be used instead of, or along with, balloon angioplasty. Atherectomy is successful about 95% of the time; however, plaque forms again in 20–30% of patients.

Precautions

Atherectomy should not be performed when the plaque is located where blood vessels divide into branches, when plaque is angular or inside an angle of a blood vessel, on patients with weak vessel walls, on ulcerated or calcium-hardened lesions, or on blockages through which a guide wire will not pass. Laser artherectomy has less successful outcomes in individuals with diabetes or renal failure, and usually is not the procedure of choice for these patients.

Preparation

The day before atherectomy, the patient takes medication to prevent blood clots and may be asked to bathe and shampoo with an antiseptic skin cleaner.

Aftercare

After the procedure, the patient spends several days in the hospital's cardiac monitoring area. For at least 20 minutes, pressure is applied to a dressing on the insertion site. For the first hour, an electrocardiogram (ECG) and close monitoring are conducted; vital signs are checked every 15 minutes. Pain medication is then administered. The puncture site is checked once an hour or more. For most of the first 24 hours, the patient remains in bed.

Risks

Chest pain is the most common complication of atherectomy. Other common complications are injury to the blood vessel lining, plaque that re-forms, the development of blood clots, and bleeding at the site of catheter insertion. More serious but less frequent complications are blood vessel holes, blood vessel wall tears, or reduced blood flow through the artery.

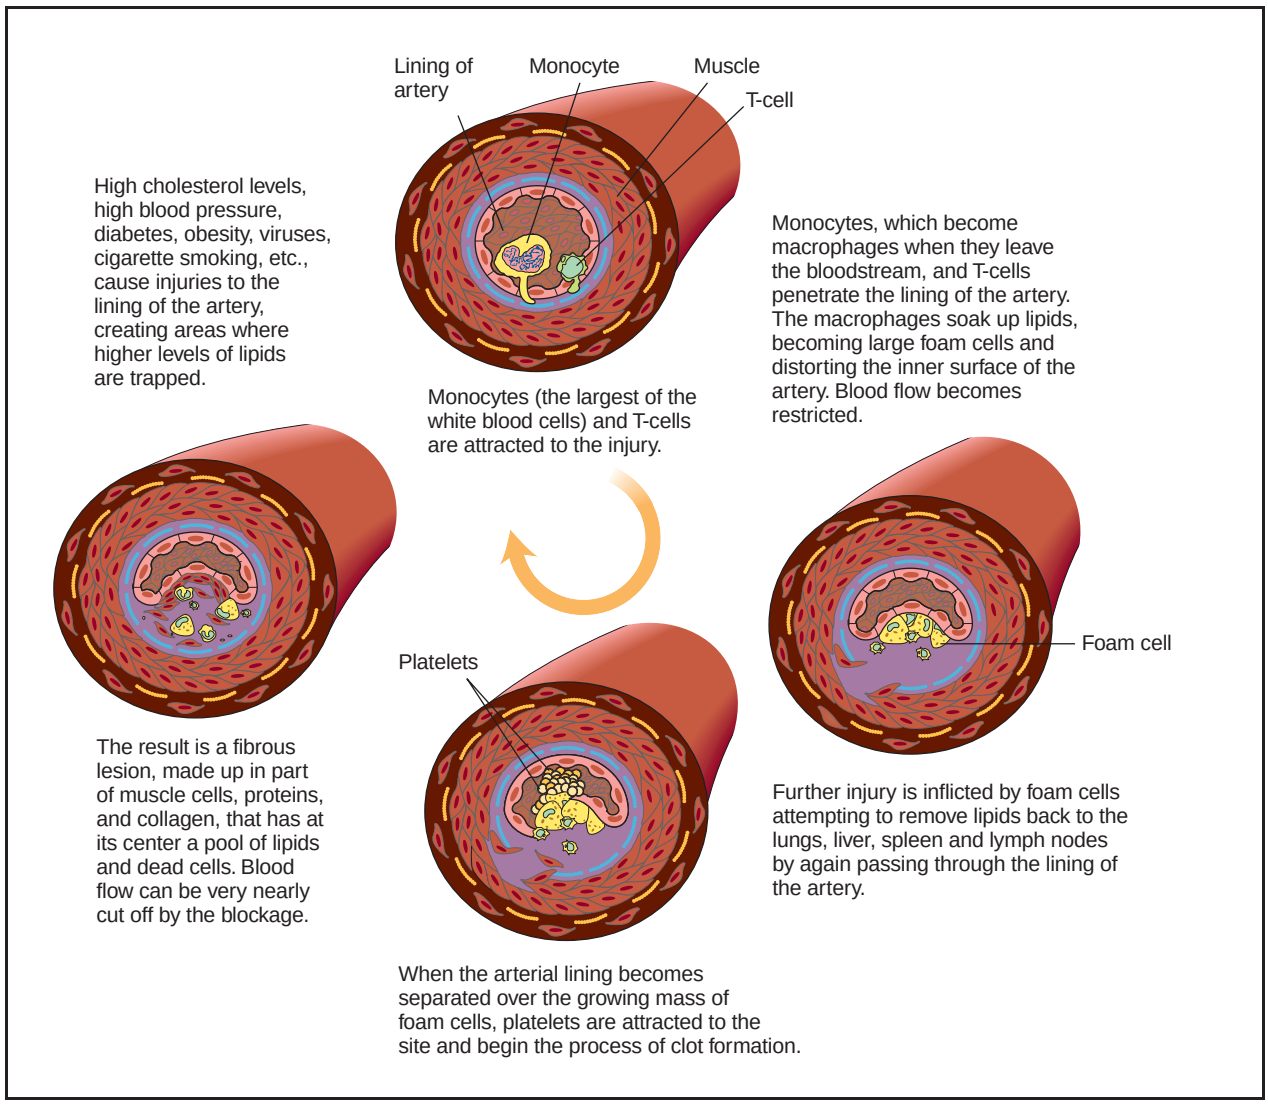
Atherosclerosis

Definition

Atherosclerosis is the buildup of a waxy plaque on the inside of blood vessels. In Greek, *athere* means *gruel*, and *skleros* means *hard*. Atherosclerosis is

WWW.BOOKBAZ.IR



The progression of atherosclerosis. *(Illustration by Hans & Cassady, Inc. © Cengage Learning®.)*

often called arteriosclerosis. Arteriosclerosis (from the Greek *arteria,* meaning *artery*) is a general term for hardening of the arteries. Arteriosclerosis can occur in several forms, including atherosclerosis.

Demographics

Atherosclerosis is a slow, progressive condition that may occur anywhere in the body but it usually affects large and medium sized arteries. It can begin in the late teens, but it usually takes decades to cause symptoms. Some people experience rapidly progressing atherosclerosis during their thirties, others during their fifties or sixties. Over time, the buildup of the waxy plaque can cause narrowing of coronary arteries in the heart. Atherosclerosis, (the narrowing of coronary arteries due to this plaque buildup), causes more than 90% of heart attacks.

Due to the slow, progressive, and often times asymptomatic nature of the condition, it is difficult to accurately determine the frequency of atherosclerosis, but the estimated prevalence is that approximately 4.6 million people in the United States are managing various clinical manifestations of this disease.

Description

Atherosclerosis, a progressive process largely responsible for heart disease, is a type of arteriosclerosis or hardening of the arteries. An artery is made up of several layers: an inner lining called the endothelium, an

elastic membrane that allows the artery to expand and contract, a layer of smooth muscle, and a layer of connective tissue. Arteriosclerosis is a broad term that includes a hardening of the inner and middle layers of the artery. It can be caused by normal aging, by high blood pressure, and by diseases such as diabetes. Atherosclerosis is a type of arteriosclerosis that affects only the inner lining of an artery. It is characterized by plaque deposits that block the flow of blood.

Plaque is made of fatty substances, cholesterol, waste products from the cells, calcium, and fibrin, a stringy material that helps clot blood. The plaque formation process stimulates the cells of the artery wall to produce substances that accumulate in the inner layer. Fat builds up within these cells and around them, and they form connective tissue and calcium. The inner layer of the artery wall thickens, the artery's diameter is reduced, and blood flow and oxygen delivery are decreased. Plaques can rupture or crack open, causing the sudden formation of a blood clot (thrombosis). Atherosclerosis can cause a heart attack if it completely blocks the blood flow in the heart (coronary) arteries. It can cause a stroke if it completely blocks the brain (carotid) arteries. Atherosclerosis can also occur in the arteries of the neck, kidneys, thighs, and arms, causing kidney failure or gangrene and amputation.

KEY TERMS

Arteriosclerosis—Hardening of the arteries. It includes atherosclerosis, but the two terms are often used synonymously.

Cholesterol—A fat-like substance that is made by the human body and eaten in animal products. Cholesterol is used to form cell membranes and process hormones and vitamin D. High cholesterol levels contribute to the development of atherosclerosis.

HDL Cholesterol—Refers to about one-third or one-fourth of all cholesterol, called high-density lipoprotein cholesterol. High levels of HDL, nicknamed "good" cholesterol, decrease the risk of atherosclerosis.

LDL Cholesterol—Refers to the primary cholesterol molecule, called Low-density lipoprotein cholesterol. High levels of LDL, nicknamed "bad" cholesterol, increase the risk of atherosclerosis

Plaque—A deposit of fatty and other substances that accumulates in the lining of the artery wall.

Triglyceride—A fat that comes from food or is made from other energy sources in the body.

Causes and symptoms

Atherosclerosis is complex. Its exact cause is still unknown. It is thought that atherosclerosis is caused by a response to damage to the endothelium from high cholesterol, high blood pressure, and cigarette smoking. A person who has all three of these risk factors is eight times more likely to develop atherosclerosis than is a person who has none. Physical inactivity, diabetes, and obesity are also risk factors for atherosclerosis. High levels of the amino acid homocysteine and abnormal levels of protein-coated fats called lipoproteins also raise the risk of coronary artery disease. These substances are the targets of much current research. The role of triglycerides, another fat that circulates in the blood, in forming atherosclerotic plaques is unclear. High levels of triglycerides are often associated with diabetes, obesity, and low levels of high-density lipoproteins (HDL cholesterol). The more HDL ("good") cholesterol, in the blood, the less likely is coronary artery disease. These risk factors are all modifiable. Non-modifiable risk factors are heredity, sex, and age.

Risk factors that can be changed:

- Cigarette/tobacco smoke—Smoking increases both the chance of developing atherosclerosis and the chance of dying from coronary heart disease. Second hand smoke may also increase risk.
- High blood cholesterol—Cholesterol, a soft, waxy substance, comes from foods such as meat, eggs, and other animal products and is produced in the liver. Age, sex, heredity, and diet affect cholesterol. Total blood cholesterol is considered high at levels above 240 mg/dL and borderline at 200-239 mg/dL. High-risk levels of low-density lipoprotein (LDL cholesterol) begin at 130-159 mg/dL.
- High triglycerides—Most fat in food and in the body takes the form of triglycerides. Blood triglyceride levels above 400 mg/dL have been linked to coronary artery disease in some people. Triglycerides, however, are not nearly as harmful as LDL cholesterol.
- High blood pressure—Blood pressure of 140 over 90 or higher makes the heart work harder, and over time, both weakens the heart and harms the arteries.
- Physical inactivity—Lack of exercise increases the risk of atherosclerosis.

WWW.BOOKBAZ.IR

- Diabetes mellitus—The risk of developing atherosclerosis is seriously increased for diabetics and can be lowered by keeping diabetes under control. Most diabetics die from heart attacks caused by atherosclerosis.
- Obesity—Excess weight increases the strain on the heart and increases the risk of developing atherosclerosis even if no other risk factors are present.

Risk factors that cannot be changed:

- Heredity—People whose parents have coronary artery disease, atherosclerosis, or stroke at an early age are at increased risk. The high rate of severe hypertension among African-Americans puts them at increased risk.
- Sex—Before age 60, men are more likely to have heart attacks than women. After age 60, the risk is equal among men and women.
- Age—Risk is higher in men who are 45 years of age and older and women who are 55 years of age and older.

Symptoms differ depending upon the location of the atherosclerosis.

- In the coronary (heart) arteries: Chest pain, heart attack, or sudden death.
- In the carotid (brain) arteries: Sudden dizziness, weakness, loss of speech, or blindness.
- In the femoral (leg) arteries: Disease of the blood vessels in the outer parts of the body (peripheral vascular disease) causes cramping and fatigue in the calves when walking.
- In the renal (kidney) arteries: High blood pressure that is difficult to treat.

Diagnosis

Physicians may be able to make a diagnosis of atherosclerosis during a physical exam by means of a stethoscope and gentle probing of the arteries with the hand (palpation). More definite tests are electrocardiography, echocardiography or ultrasonography of the arteries (for example, the carotids), radionuclide scans, and angiography.

An electrocardiogram shows the heart's activity. Electrodes covered with conducting jelly are placed on the patient's body. They send impulses of the heart to a recorder. The test takes about 10 minutes and is performed in a physician's office. Exercise electrocardiography (stress test) is conducted while the patient exercises on a treadmill or a stationary bike. It is performed in a physician's office or an exercise laboratory and takes 15-30 minutes.

Echocardiography, cardiac ultrasound, uses sound waves to create an image of the heart's chambers and valves. A technician applies gel to a handheld transducer, presses it against the patient's chest, and images are displayed on a monitor. This technique cannot evaluate the coronary arteries directly. They are too small and are in motion with the heart. Severe coronary artery disease, however, may cause abnormal heart motion that is detected by echocardiography. Performed in a cardiology outpatient diagnostic laboratory, the test takes 30-60 minutes. Ultrasonography is also used to assess arteries of the neck and thighs.

Radionuclide angiography and thallium (or sestamibi) scanning enable physicians to see the blood flow through the coronary arteries and the heart chambers. Radioactive material is injected into the bloodstream. A device that uses gamma rays to produce an image of the radioactive material (gamma camera) records pictures of the heart. Radionuclide angiography is usually performed in a hospital's nuclear medicine department and takes 30–60 minutes. Thallium scanning is usually done after an exercise stress test or after injection of a vasodilator, a drug to enlarge the blood vessels, like dipyridamole (Persantine). Thallium is injected, and the scan is done then and again four hours (and possibly 24 hours) later. Thallium scanning is usually performed in a hospital's nuclear medicine department. Each scan takes 30-60 minutes.

Coronary angiography is the most accurate diagnostic method and the only one that requires entering the body (invasive procedure). A cardiologist inserts a catheter equipped with a viewing device into a blood vessel in the leg or arm and guides it into the heart. The patient has been given a contrast dye that makes the heart visible to x rays. Motion pictures are taken of the contrast dye flowing though the arteries. Plaques and blockages, if present, are well defined. The patient is awake but has been given a sedative. Coronary angiography is performed in a cardiac catheterization laboratory and takes from 30 minutes to two hours.

Treatment

Treatment includes lifestyle changes, lipid-lowering drugs, percutaneous transluminal coronary angioplasty, and coronary artery bypass surgery. Atherosclerosis requires lifelong care.

Patients who have less severe atherosclerosis may achieve adequate control through lifestyle changes and drug therapy. Many of the lifestyle changes that prevent disease progression—a low-fat, low-cholesterol

diet, losing weight (if necessary), exercise, controlling blood pressure, and not smoking—also help prevent the disease.

Most of the drugs prescribed for atherosclerosis seek to lower cholesterol. Many popular lipid-lowering drugs can reduce LDL-cholesterol by an average of 25-30% when combined with a low-fat, low-cholesterol diet. Lipid-lowering drugs include bile acid resins, "statins" (drugs that effect HMG-CoA reductase, an enzyme that controls the processing of cholesterol), niacin, and fibric acid derivatives such as gemfibrozil (Lobid). Aspirin helps prevent thrombosis and a variety of other medications can be used to treat the effects of atherosclerosis.

Percutaneous transluminal coronary angioplasty and bypass surgery are invasive procedures that improve blood flow in the coronary arteries. Percutaneous transluminal coronary angioplasty (coronary angioplasty) is a non-surgical procedure in which a catheter tipped with a balloon is threaded from a blood vessel in the thigh into the blocked artery. The balloon is inflated, compresses the plaque to enlarge the blood vessel, and opens the blocked artery. Coronary angioplasty is performed by a cardiologist in a hospital and generally requires a hospital stay of one or two days. It is successful about 90% of the time, but for one-third of patients the artery narrows again within six months. It can be repeated and a "stent" may be placed in the artery to help keep it open.

In coronary artery bypass surgery (bypass surgery), a detour is built around the blockage with a healthy vein or artery, which then supplies oxygen-rich blood to the heart. It is major surgery appropriate for patients with blockages in two or three major coronary arteries or severely narrowed left main coronary arteries, and for those who have not responded to other treatments. It is performed in a hospital under general anesthesia and uses a heart-lung machine. About 70% of patients experience full relief; about 20% partial relief.

Three other semi-experimental surgical procedures may be used to treat atherosclerosis. In atherectomy, a cardiologist shaves off and removes strips of plaque from the blocked artery. In laser angioplasty, a catheter with a laser tip is inserted to burn or break down the plaque. A metal coil called a stent may be permanently implanted to keep a blocked artery open.

Alternatives

Alternative therapies that focus on diet and lifestyle can help prevent, retard, or reverse atherosclerosis. Herbal therapies that may be helpful include: hawthorn (*Crataegus laevigata*), notoginseng root (*Panax notoginseng*), garlic (*Allium sativum*), ginger (*Zingiber officinale*), hot red or chili peppers, yarrow (*Achillea millefolium*), and alfalfa (*Medicago sativum*). Relaxation techniques including yoga, meditation, guided imagery, biofeedback, and counseling and other "talking" therapies may also be useful to prevent or slow the progress of the disease. Dietary modifications focus on eating foods that are low in fats (especially saturated fats), cholesterol, sugar, and animal proteins and high in fiber and antioxidants (found in fresh fruits and vegetables). Liberal use of onions and garlic is recommended, as is eating raw and cooked fish, especially cold-water fish like salmon. Smoking, alcohol, and stimulants like coffee should be avoided. Chelation therapy, which uses anticoagulant drugs and nutrients to dissolve plaque and flush it through the kidneys, is controversial. Long-term remedies can be prescribed by specialists in ayurvedic medicine, which combines diet, herbal remedies, relaxation and exercise, and homeopathy.

Prognosis

Atherosclerosis can be successfully treated but not cured. Recent clinical studies have shown that atherosclerosis can be delayed, stopped, and even reversed by aggressively lowering LDL cholesterol. New diagnostic techniques enable physicians to identify and treat atherosclerosis in its earliest stages. New technologies and surgical procedures have extended the lives of many patients who would otherwise have died.

Prevention

A healthy lifestyle—eating right, regular exercise, maintaining a healthy weight, not smoking, and controlling hypertension—can reduce the risk of developing atherosclerosis, help keep the disease from progressing, and sometimes cause it to regress.

- Eat right-A healthy diet reduces excess levels of LDL cholesterol and triglycerides. It includes a variety of foods that are low in fat and cholesterol and high in fiber; plenty of fruits and vegetables; and limited sodium. Fat should comprise no more than 30%, and saturated fat no more than 8-10%, of total daily calories according to the American Heart Association. Cholesterol should be limited to about 300 milligrams per day and sodium to about 2,400 milligrams. The "Food Guide" Pyramid developed by the U.S. Departments of Agriculture and Health and Human Services provides daily guidelines: 6-11

WWW.BOOKBAZ.IR

servings of bread, cereal, rice, and pasta; 3-5 servings of vegetables; 2-4 servings of fruit; 2-3 servings of milk, yogurt, and cheese; and 2-3 servings of meat, poultry, fish, dry beans, eggs, and nuts. Fats, oils, and sweets should be used sparingly. Mono-unsaturated oils, like olive and rapeseed (Canola) are good alternatives to use for cooking.

- Exercise regularly—Aerobic exercise can lower blood pressure, help control weight, and increase HDL ("good") cholesterol. It may keep the blood vessels more flexible. Moderate to intense aerobic exercise lasting about 30 minutes (or three 10-minute exercise periods) four or more times per week is recommended, according to the Centers for Disease Control and Prevention and the American College of Sports Medicine. Aerobic exercise includes walking, jogging, and cycling, active gardening, climbing stairs, or brisk housework. A physician should be consulted before exercise if a person has atherosclerosis or is at increased risk for it.
- Maintain a desirable body weight—Losing weight can help reduce total and LDL cholesterol, reduce triglycerides, and boost HDL cholesterol. It may also reduce blood pressure. Eating right and exercising are two key components in maintaining a desirable body weight.
- Do not smoke or use tobacco—Smoking has many adverse effects on the heart but quitting can repair damage. Ex-smokers face the same risk of heart disease as non-smokers within five to 10 years of quitting. Smoking is the worst thing a person can do to their heart and lungs.
- Seek treatment for hypertension—High blood pressure can be controlled through lifestyle changes—reducing sodium and fat, exercising, managing stress, quitting smoking, and drinking alcohol in moderation—and medication. Drugs that provide effective treatment are: diuretics, beta blockers, sympathetic nerve inhibitors, vasodilators, angiotensin converting enzyme (ACE) inhibitors, and calcium antagonists. Hypertension usually has no symptoms so it must be checked to be known. Like cholesterol, hypertension is called a "silent killer."

REVISED BY LAURA JEAN CATALDO, RN, Ed.D.

Athetosis *see* **Movement disorders**

Athlete's foot

Definition

A common fungus infection between the toes in which the skin becomes itchy and sore, cracking and peeling away. Athlete's foot (also known as *tinea pedis* or foot **ringworm**) can be treated, but it can be tenacious and difficult to clear up completely.

Description

Athlete's foot is a very common condition of itchy, peeling skin on the feet. In fact, it is so common that most people will have at least one episode at least once in their lives. It is less often found in women and children under age 12. (Symptoms that look like athlete's foot in young children most probably are caused by some other skin condition.)

Because the fungi grow well in warm, damp areas, they flourish in and around swimming pools, showers, and locker rooms. *Tinea pedis* got its common name because the infection was common among athletes who often used these areas.

Causes and symptoms

Athlete's foot is caused by a fungal infection that most often affects the fourth and fifth toe webs. *Trichophyton rubrum*, *T. mentagrophytes*, and *Epidermophyton floccosum*, the fungi that cause athlete's foot, are unusual in that they live exclusively on dead body tissue (hair, the outer layer of skin, and nails). The fungus grows best in moist, damp, dark places with poor ventilation. The problem doesn't occur among people who usually go barefoot.

Athlete's foot fungus on toes of patient. *(Custom Medical Stock Photo, Inc.)*

Many people carry the fungus on their skin. However, it will only flourish to the point of causing athlete's foot if conditions are right. Many people believe athlete's foot is highly contagious, especially in public swimming pools and shower rooms. Research has shown, however, that it is difficult to pick up the infection simply by walking barefoot over a contaminated damp floor. Exactly why some people develop the condition and others don't is not well understood.

Sweaty feet, tight shoes, synthetic socks that do not absorb moisture well, a warm climate, and not drying the feet well after swimming or bathing, all contribute to the overgrowth of the fungus.

Symptoms of athlete's foot include itchy, sore skin on the toes, with scaling, cracking, inflammation, and blisters. Blisters that break, exposing raw patches of tissue, can cause **pain** and swelling. As the infection spreads, **itching** and burning may get worse.

If it is not treated, athlete's foot can spread to the soles of the feet and toenails. Stubborn toenail infections may appear at the same time, with crumbling, scaling and thickened nails, and nail loss. The infection can spread further if patients scratch and then touch themselves elsewhere (especially in the groin or under the arms). It is also possible to spread the infection to other parts of the body via contaminated bed sheets or clothing.

Diagnosis

Not all foot **rashes** are athlete's foot, which is why a physician should diagnose the condition before any remedies are used. Using nonprescription products on a rash that is not athlete's foot could make the rash worse.

A dermatologist can diagnose the condition by **physical examination** and by examining a preparation of skin scrapings under a microscope. This test, called a KOH preparation, treats a sample of tissue scraped from the infected area with heat and potassium hydroxide (KOH). This treatment dissolves certain substances in the tissue sample, making it possible to see the fungi under the microscope.

Treatment

Athlete's foot may be resistant to medication and should not be ignored. Simple cases usually respond well to antifungal creams or sprays (clotrimazole, ketoconazole, miconazole nitrate, sulconazole nitrate, or tolnaftate). If the infection is resistant to

WWW.BOOKBAZ.IR

Athlete's foot fungus on bottom of patient's foot. *(Custom Medical Stock Photo, Inc.)*

topical treatment, the doctor may prescribe an oral antifungal drug.

Untreated athlete's foot may lead to a secondary bacterial infection in the skin cracks.

Alternatives

A footbath containing cinnamon has been shown to slow down the growth of certain molds and fungi, and is said to be very effective in clearing up athlete's foot. To make the bath, do the following:

- heat four cups of water to a boil
- add eight to 10 broken cinnamon sticks
- reduce heat and simmer five minutes
- remove and let the mixture steep for 45 minutes until lukewarm
- soak feet

Other herbal remedies used externally to treat athlete's foot include: a foot soak or powder containing goldenseal (*Hydrastis canadensis*); tea tree oil (*Melaleuca* spp.); or calendula (*Calendula officinalis*) cream to help heal cracked skin.

Prognosis

Athlete's foot usually responds well to treatment, but it is important to take all medication as directed by a dermatologist, even if the skin appears to be free of fungus. Otherwise, the infection could return. The toenail infections that may accompany athlete's foot, however, are typically very hard to treat effectively.

Prevention

Good personal hygiene and a few simple precautions can help prevent athlete's foot. To prevent spread of athlete's foot, do the following:

- wash feet daily
- dry feet thoroughly (especially between toes)
- avoid tight shoes (especially in summer)
- wear sandals during warm weather
- wear cotton socks and change them often if they get damp
- do not wear socks made of synthetic material
- go barefoot outdoors when possible
- wear bathing shoes in public bathing or showering areas
- use a good quality foot powder
- do not wear sneakers without socks
- wash towels, contaminated floors, and shower stalls well with hot soapy water if anyone in the family has athlete's foot.

Carol A. Turkington

Athletic heart syndrome

Definition

Athletic heart syndrome (AHS) is the adaptation of an athlete's heart in response to the physiologic stresses of rigorous physical training. Common in athletes, AHS is characterized by the enlargement of the heart, along with a lower-than-normal resting heart rate. It can be difficult to distinguish a significant medical condition from an athletic heart. Although AHS is not harmful to athletes, it does cause those peoples's hearts to enlarge. AHS is also called by the following terms: athlete's heart syndrome (or athlete's heart), athletic bradycardia, and exercise-induced cardiomegaly.

Description

Athletic heart syndrome occurs in people who **exercise** or train strenuously for over one hour a day for most days of the week. Such training can involve activities for endurance sports. The heart adapts to

physical demands by enlarging, especially the left ventricle. Enlargement increases the cardiac output, the amount of blood pumped with each beat of the heart. The exact type of adaptation depends on the nature of the physical demand. There are two types of demand, static and dynamic. Static demand involves smaller groups of muscles under extreme resistance for brief periods. Examples include those exercises that promote strength training such as weight lifting. The heart's response to static training is hypertrophy, thickening of the muscle walls of the heart. As the wall of the heart adapts, there are changes in the electrical conducting system of the heart. Because of the larger volume of blood being pumped with each heartbeat, the heart rate when at rest decreases below the normal level for nonathletes.

Dynamic training involves larger groups of muscles at lower resistance for extended periods. Examples are those exercises that involve endurance training such as aerobic training, cycling, swimming, and playing tennis. As such, cardiac enlargement is associated with dynamic training.

Sudden unexpected death (SUD) syndrome is the death of an athlete, usually during or shortly after physical activity. It is not associated with athletic heart syndrome. Often, there is no warning that the person will experience SUD, although in some cases, warning signs appear that cause the person to seek medical advice. Importantly, cases of death occurring during physical activity are not caused by athletic heart syndrome but by undiagnosed heart disorders.

Demographics

Evidence for enlarged hearts in athletes has been recognized by the medical community since as early as the late nineteenth century. In 1899, for instance, the Swedish neurologist Salomon Eberhard Henshen (1847–1930), from the University of Uppsala (Sweden), published the article "A Study in Sports Medicine, Skiing and Competitive Skiing," in which he identified that athletes develop enlarged hearts as the result of rigorous exercise. Henshen compared the sizes of hearts in cross-country skiers with those of people who lived sedentary lifestyles. His conclusion was that enlarged hearts in athletes was a normal consequence of their athletic lifestyles. At about this same time, the American doctor Eugene A. Darling, of Harvard University in Cambridge, Massachusetts, studied the parallel between heart enlargement and the strenuous activities of rowers at the university. Darling came up with the same result as did Henshen. Other studies in the late 1800s and early 1900s also documented cardiac enlargement in people who exercised more than the average person but without any medical problems with cardiovascular disease.

Henshen's and Darling's results were not generally accepted as valid by the medical community at the time they were reported. In fact, some physicians contended that cardiac enlargement in athletes would eventually lead to a collapse of the cardiovascular system. However, later research substantiated their work that the heart increased in size with athletic activities, especially with regards to endurance events that required large aerobic actions.

During the last few decades of the twentieth century and into the second decade of the twenty-first century, research has shown that men and women have similar enlargement of the heart with regular exercise. However, studies have shown that female athletes have less enlargement of the heart than do males (after taking into account the smaller female body). As of 2014, the reason for this difference was not known. In addition, race is a factor in heart enlargement and athletic heart syndrome. Overall, studies have found that athletes of African descent tend to have thicker left ventricle walls than do white athletes.

Causes and symptoms

Athletic heart syndrome is the consequence of a normal adaptation by the heart to increased physical activity. During times of prolonged, intense physical activity, the brain tells the heart to pump more blood to prevent a depletion of oxygen in the blood coursing through the body. Over time, the heart enlarges, especially the left ventricle, and the thickness and muscle mass in and around the heart increases. The left ventricle may increase by as much as 20% of its normal volume.

In addition, changes in the electrical conduction system of the heart may be pronounced and diagnostic but should not cause problems. Other than this change, AHS normally does not have any physical symptoms, other than the following four primary signs:

- a consistently lower-than-normal rate for the resting heart, what is called bradycardia
- an enlarged heart, which is called cardiomegaly
- the thickening of the muscular wall of the heart, especially within the left ventricle (the portion of the heart that pumps oxygenated blood into the aorta), what is called cardiac hypertrophy
- an abnormal reading on an electrocardiogram, which is caused by electrical impulses taking irregular routes across the heart

WWW.BOOKBAZ.IR

When athletes have bradycardia, their normal resting heart rate is from 40 to 60 beats per minute and sometimes as low as 35 to 50 beats per minute. When athletes train and perform strenuously and for long periods (such as for longer than five hours at a time), additional blood and oxygen is needed for the functioning of the tissues within the arms and legs. A larger heart is the normal consequence of such activities, which results in a higher output for the heart. Because of this increased output, the heart can work more slowly, resulting in the lower resting heart rate.

Occasionally, AHS may involve an irregular heartbeat. For instance, athletes may develop what is called third heart sound, commonly called S3 gallop. When this occurs an extra heart sound is heard when a doctor listens to the person's heart with a stethoscope or other listening device. Besides the normal S_1 and S_2 ("lub-dub") heart sounds, the doctor may also hear a S_3 heart sound. This extra sound is associated with an abnormally shaped heart that is filling with blood.

With respect to SUD, other heart problems are involved. Further, in a large majority of SUD cases, an underlying structural defect of the heart has been noted.

Diagnosis

Athletic heart syndrome is usually discovered during a regular **physical examination** or when testing is being performed for unrelated medical problems. The changes in the heartbeat caused by the electrical conduction system of the heart are detectable on an electrocardiogram (ECG). Detection is also possible through a chest x ray, which can pinpoint increased heart size, and an echocardiogram, which can determine the size and shape of the heart and its chambers along with distinguishing between pathological and physiological reasons for the abnormally large heart.

Many of the changes seen in athletic heart syndrome mimic those of various heart diseases. For instance, **hypertrophic cardiomyopathy** (HCM; a disease found within the myocardium, or the muscle of the heart) and AHS are similar in their symptoms. HCM is a thickening of the myocardium without any known medical reason. It can cause **sudden cardiac death** in young athletes. Thus, careful examination must be made to distinguish **heart disease** from athletic heart syndrome.

Treatment

AHS is not a dangerous medical condition for athletes. Sudden cardiac death can cause athletes to die during or after strenuous physical activities, but AHS is not associated with this problem. Generally, treatment is not necessary for athletes with AHS. Research has shown that athletes are not at a heightened risk for medical problems or sudden cardiac death if they have athletic heart syndrome. However, it is imperative that athletes with any of the symptoms associated with AHS have a complete examination to make sure they really have AHS—and not a serious medical problem. Athletic heart syndrome can have the same symptoms as life-threatening medical disorders such as **congenital heart disease**. If individuals have been diagnosed with AHS but begin to have symptoms involving chest pains and light-headedness, along with episodes of losing consciousness, then they should seek diagnosis and treatment.

KEY TERMS

Bradycardia—Referring to a resting heart rate of under 60 beats per minute.

Cardiac hypertrophy—Thickening of the heart muscle.

Cardiomegaly—Referring to a condition in which the heart is larger than normal.

Hypertrophy—An increase in the size of an organ, such as the heart.

Sudden unexpected death syndrome (SUD)—Sometimes called sudden unexpected nocturnal death syndrome, the abrupt, unforeseen death of an adolescent or adult, often during sleep.

Ventricle—Either one of two lower chambers (left and right) of the heart that receives blood from the upper chambers (atria) and then pumps that blood into the arteries.

Prognosis

No adverse medical problems are known to be caused by athletic heart syndrome. However, AHS is closely associated with the symptoms of cardiac disease and other related medical problems. Because of this similarity, athletes can become disqualified for athletic events if they are diagnosed with a medical problem that is really only AHS. For this reason, it is important to properly diagnosis whether an athlete has AHS or is suffering from a specific type of cardiac disease. For instance, hypertrophic **cardiomyopathy** is the most common cause of sudden death in young athletes competing in different physical events. However, AHS does not have anything to do with a

diagnosis of hypertrophic cardiomyopathy. The best way to make such a distinction is with the use of **echocardiography** and other noninvasive imaging techniques. Without the presence of heart problems, athletes with athletic heart syndrome should expect to live a normal life.

Prevention

Athletic heart syndrome can only be prevented by avoiding prolonged and strenuous physical activities. However, exercise is important to one's health so having an enlarged heart is no concern when other medical problems are not present. Thus, it is advised to maintain a regular exercise program in order to keep a healthy heart.

Atopic dermatitis

Definition

Eczema is a general term used to describe a variety of conditions that cause an itchy, inflamed skin rash. Atopic **dermatitis**, a form of eczema, is a non-contagious disorder characterized by chronically inflamed skin and sometimes intolerable **itching**.

Description

Atopic dermatitis refers to a wide range of diseases that are often associated with **stress** and allergic disorders that involve the respiratory system, like **asthma** and hay **fever**. Although atopic dermatitis can appear at any age, it is most common in children and young adults. Symptoms usually abate before the age of 25 and do not affect the patient's general health.

About one in ten babies develop a form of atopic dermatitis called infantile eczema. Characterized by skin that oozes and becomes encrusted, infantile eczema most often occurs on the face and scalp. The condition usually improves before the child's second birthday, and medical attention can keep symptoms in check until that time.

When atopic dermatitis develops after infancy, inflammation, blistering, oozing, and crusting are less pronounced. The patient's sores become dry, turn from red to brownish-gray, and skin may thicken and become scaly. In dark-skinned individuals, this condition can cause the complexion to lighten or darken. Itching associated with this condition is usually worst at night. It can be so intense that patients

WWW.BOOKBAZ.IR

A close-up view of atopic dermatitis in the crook of the elbow of a 12-year-old patient. *(Custom Medical Stock Photo, Inc.)*

scratch until their sores bleed, sometimes causing scarring and infection.

Atopic dermatitis affects about 3% of the population of the United States, and about 80% of the people who have the condition have one or more relatives with the same condition or a similar one. Symptoms tend to be most severe in females. Atopic dermatitis can erupt on any part of the skin, and crusted, thickened patches on the fingers, palms, or the soles of the feet can last for years. In teenagers and young adults, atopic dermatitis often appears on one or more of the following areas:

- elbow creases
- backs of the knees
- ankles
- wrists
- face
- neck
- upper chest
- palms and between the fingers

Causes and symptoms

While allergic reactions often trigger atopic dermatitis, the condition is thought to be the result of an inherited over-active immune system or a genetic defect that causes the skin to lose abnormally large amounts of moisture. The condition can be aggravated by a cycle that develops in which the skin itches, the patient scratches, the condition worsens, the itching worsens, the patient scratches, etc. This cycle must be broken by relieving the itching to allow the skin time to heal. If the skin becomes broken, there is also a risk of developing skin infections which, if not recognized and treated promptly, can become more serious.

Symptoms of atopic dermatitis include the following:

- an itchy rash and dry, thickened skin on areas of the body where moisture can be trapped
- continual scratching
- chronic fatigue, caused when itching disrupts sleep

An individual is more at-risk for developing the condition if there is a personal or family history of atopic dermatitis, hay fever, asthma, or other **allergies**. Exposure to any of the following can cause a flare-up:

- hot or cold temperatures
- wool and synthetic fabrics
- detergents, fabric softeners, and chemicals
- use of drugs that suppress immune-system activity

Certain foods, such as peanuts, cow's milk, eggs, and fish, can trigger symptoms of atopic dermatitis. A small percentage of patients with atopic dermatitis find that their symptoms worsen after having been exposed to dust, feather pillows, rough-textured fabrics, or other materials to which dust adheres.

Diagnosis

Diagnosis of atopic dermatitis is usually based on the patient's symptoms and personal and family **health history**. Skin tests do not generally provide reliable information about this condition.

Treatment

Atopic dermatitis cannot be cured, but the severity and duration of symptoms can be controlled. A dermatologist should be consulted when symptoms

KEY TERMS

Corticosteroid—A steroid hormone produced by the adrenal gland or as a synthetic compound that reduces inflammation, redness, rashes, and irritation.

Dermatitis—Inflammation of the skin.

first appear, and is likely to recommend warm baths to loosen encrusted skin, followed by applications of petroleum jelly or vegetable shortening to prevent the skin's natural moisture from escaping.

Externally applied (topical) **steroids** or preparations containing coal tar can relieve minor itching, but coal tar has an unpleasant odor, stains clothes, and may increase skin-cancer risk. Excessive use of steroid creams in young children can alter growth. Pregnant women should not use products that contain coal tar. Topical steroids can cause itching, burning, **acne**, permanent stretch marks, and thinning and spotting of the skin. Applying topical steroids to the area around the eyes can cause **glaucoma**.

Oral **antihistamines**, such as diphenhydramine (Benadryl), can relieve symptoms of allergy-related atopic dermatitis. More concentrated topical steroids are recommended for persistent symptoms. A mild tranquilizer may be prescribed to reduce stress and help the patient sleep, and **antibiotics** are used to treat secondary infections.

Cortisone ointments should be used sparingly, and strong preparations should never be applied to the face, groin, armpits, or rectal area. Regular medical monitoring is recommended for patients who use cortisone salves or lotions to control wide-spread symptoms. Oral cortisone may be prescribed if the patient does not respond to other treatments, but patients who take the medication for more than two weeks have a greater-than-average risk of developing severe symptoms when the treatment is discontinued.

Allergy shots rarely improve atopic dermatitis and sometimes aggravate the symptoms. Since **food allergies** may trigger atopic dermatitis, the doctor may suggest eliminating certain foods from the diet if other treatments prove ineffective.

If symptoms are extremely severe, ultraviolet **light therapy** may be prescribed, and a wet body wrap recommended to help the skin retain moisture. This technique, used most often with children, involves sleeping in a warm room while wearing wet pajamas under dry clothing, rain gear, or a nylon sweatsuit. The patient's face may be covered with wet gauze covered by elastic bandages, and his or her hands encased in wet socks covered by dry ones.

A physician should be notified if the condition is widespread or resists treatment, or the skin oozes, becomes encrusted, or smells, as this may indicate an infection.

Alternatives

Alternative therapies can sometimes bring relief or resolution of atopic dermatitis when conventional therapies are not helping. If the condition becomes increasingly widespread or infected, a physician should be consulted.

Helpful alternative treatments for atopic dermatitis may include:

- Taking regular brisk walks, followed by bathing in warm water sprinkled with essential oil of lavender (*Lavandula officinalis*); lavender oil acts as a nerve relaxant for the whole body including the skin
- Supplementing the diet daily with zinc, fish oils, vitamin A, vitamin E, and evening primrose oil (*Oenothera biennis*)–all good sources of nutrients for the skin
- Reducing or eliminating red meat from the diet
- Eliminating or rotating potentially allergic foods such as cow's milk, peanuts, wheat, eggs, and soy
- Implementing stress reduction techniques in daily life.

Herbal therapies also can be helpful in treating atopic dermatitis. Western herbal remedies used in the treatment of this condition include burdock (*Arctium lappa*) and *Ruta* (*Ruta graveolens*). Long-term herbal therapy requires monitoring and should be guided by an experienced practitioner.

Other alternative techniques that may be useful in the treatment of atopic dermatitis include:

- Acupressure (acupuncture without needles) to relieve tension that may trigger a flare
- Aromatherapy, using essential oils like lavender, thyme (*Thymus vulgaris*), jasmine (*Jasminum officinale*) and chamomile (*Matricaria recutita*) in hot water, to add a soothing fragrance to the air
- Shiatsu massage and reflexology, performed by licensed practitioners, to alleviate symptoms by restoring the body's natural balance
- Homeopathy, which may temporarily worsen symptoms before relieving them, should be supervised by a trained alternative healthcare professional
- Hydrotherapy, which uses water, ice, liquid, and steam, to stimulate the immune system

WWW.BOOKBAZ.IR

- Juice therapy to purify the liver and relieve bowel congestion
- Yoga to induce a sense of serenity

Prognosis

Atopic dermatitis is unpredictable. Although symptoms occur less often with age and sometimes disappear altogether, they can recur without warning. Atopic dermatitis lowers resistance to infection and increases the risk of developing **cataracts**. Sixty percent of patients with atopic dermatitis will experience flares and remissions throughout their lives.

Prevention

Research has shown that babies weaned from breast milk before they are four months old are almost three times more likely than other babies to develop recurrent eczema. Feeding eggs or fish to a baby less than one year old can activate symptoms, and babies should be shielded from such irritants as mites, molds, pet hair, and smoke.

Possible ways to prevent flare-ups include the following:

- eliminate activities that cause sweating
- lubricate the skin frequently
- avoid wool, perfumes, fabric softeners, soaps that dry the skin, and other irritants
- avoid sudden temperature changes

A doctor should be notified whenever any of the following occurs:

- fever or relentless itching develop during a flare
- an unexplained rash develops in someone who has a personal or family history of eczema or asthma
- inflammation does not decrease after seven days of treatment with an over-the-counter preparation containing coal tar or steroids
- a yellow, tan, or brown crust or pus-filled blisters appear on top of an existing rash
- a person with active atopic dermatitis comes into contact with someone who has cold sores, genital herpes, or another viral skin disease

Atrial ectopic beats

Definition

Atrial ectopic beats (AEB) refers to a contraction of the upper heart chamber which occurs before it would be expected. Atrial ectopic beats are also known as premature atrial beats, premature atrial complex (PAC), or atrial extrasystole.

Description

An AEB is usually a harmless disturbance in the normal rhythm of the heart. It can occur only occasionally, in a regular pattern, or several may occur in sequence and then disappear. Most often, the person is unaware of the event.

Causes and symptoms

As people age, extra beats tend to happen more frequently even in perfectly healthy individuals. AEB may be triggered or increased by **stress**, **caffeine**, **smoking**, and some medicines. Cold remedies containing ephedrine or pseudoephedrine have been known to increase the incidence of atrial ectopic beats. AEB may also be the result of an enlarged atria, lung disease, or the result of reduced blood supply to that area of the heart.

If a person is aware of the event, the first symptom of AEB is usually a feeling that the heart has skipped or missed a beat. This is often accompanied by a feeling that the heart is thumping or pounding in the chest. The thumping or pounding is caused by the fact that when there is an AEB, the pause before the next beat is usually longer than normal. The next beat must be stronger than usual to pump the accumulated blood out of the chamber.

Diagnosis

Diagnosis of AEB is often suspected on the basis of the patient's description of the occurrence. An electrocardiogram (ECG) can confirm the diagnosis. An ECG shows the heart beat as three wave forms. The first wave is called P, the second is called QRS, and the last is T. An atrial ectopic beat will show up on the ECG as a P wave that occurs closer than usual to the preceding T wave.

Treatment

Atrial ectopic beats do not usually require treatment. If treatment is necessary because the beats occur frequently and cause intolerable discomfort, the doctor may prescribe medication.

Prognosis

Occasional AEB usually have no significance. If they increase in frequency, they can lead to atrial tachycardia or fibrillation and to a decrease in cardiac output.

Prevention

AEB cannot usually be prevented. Aggravating factors can be addressed, like excessive stimulants and uncontrolled pulmonary disorders.

Atrial extrasystole *see* **Atrial ectopic beats**

Atrial fibrillation and flutter

Definition

Atrial fibrillation and flutter are abnormal heart rhythms in which the atria, or upper chambers of the heart, are out of sync with the ventricles, or lower chambers of the heart. In atrial fibrillation, the atria quiver chaotically and the ventricles beat irregularly. In atrial flutter, the atria beat regularly and faster than the ventricles.

Description

Atrial fibrillation and flutter are two types of cardiac **arrhythmias**, irregularities in the heart's rhythm. Nearly 2 million Americans have atrial fibrillation, according to the American Heart Association. It is the most common chronic arrhythmia. Atrial flutter is less common, but both of these arrhythmias can cause a blood clot to form in the heart. This can lead to a **stroke** or a blockage carried by the blood flow (an **embolism**) anywhere in the body's arteries. Atrial fibrillation is responsible for about 15% of strokes.

The atria are the heart's two small upper chambers. In atrial fibrillation, the heart beat is completely irregular. The atrial muscles contract very quickly and irregularly; the ventricles, the heart's two large lower chambers, beat irregularly but not as fast as the atria. When the atria fibrillate, blood that is not completely pumped out can pool and form a clot. In atrial flutter, the heart beat is usually very fast but steady. The atria beat faster than the ventricles.

Atrial fibrillation often occurs in people with various types of **heart disease**. Atrial fibrillation may also result from an inflammation of the heart's covering (**pericarditis**), chest **trauma** or surgery, pulmonary disease, and certain medications. Atrial fibrillation is more common in older people; about 10% of people over the age of 75 have it. Atrial flutter and fibrillation usually occur in people with hypertensive or coronary heart disease and other types of heart disorders.

Causes and symptoms

In most cases, the cause of atrial fibrillation and flutter can be found, but often it cannot. Causes of these heart beat abnormalities include:

- many types of heart disease
- stress and anxiety
- caffeine
- alcohol
- tobacco
- diet pills
- some prescription and over-the-counter medications
- open heart surgery

Symptoms, when present, include:

- a fluttering feeling in the chest
- a pulse that feels like the heart is skipping, racing, jumping, or is irregular
- low energy
- a faint or dizzy feeling
- pressure or discomfort in the chest
- shortness of breath
- anxiety

Diagnosis

A doctor can sometimes hear these arrhythmias using an instrument (a stethoscope) to listen to the sounds within the chest. Atrial fibrillation and flutter are usually diagnosed through **electrocardiography** (EKG), an exercise-stress test, a 24-hour Holter EKG monitor, or a telephone cardiac monitor. An EKG shows the heart's activity and may reveal a lack of oxygen (ischemia). Electrodes covered with conducting jelly are placed on the patient's chest, arms, and legs. The electrodes send impulses of the heart's activity through a monitor (called an oscilloscope) to a recorder that traces the pattern of the impulses onto paper. The test takes about 10 minutes

WWW.BOOKBAZ.IR

KEY TERMS

Arrhythmia—A variation in the normal rhythm of the heart beat. Atrial fibrillation and flutter are two types of arrhythmia.

Atria—The two small upper chambers of the heart that receive blood from the lungs and the body.

Stroke—A brain attack caused by a sudden disruption of blood flow to the brain, in this case because of a blood clot.

Ventricles—The two large lower chambers of the heart that pump blood to the lungs and to the rest of the body.

and is performed in a doctor's office. The exercise-stress test measures how the heart and blood vessels respond to work when the patient is exercising on a treadmill or a stationary bike. This test is performed in a doctor's office within an exercise laboratory and takes 15-30 minutes.

In 24-hour EKG (Holter) monitoring, the patient wears a small, portable tape recorder connected to disks on his/her chest that record the heart's rhythm during normal activities. An EKG called transtelephonic monitoring identifies arrhythmias that occur infrequently. Like **Holter monitoring**, transtelephonic monitoring continues for days or weeks and enables patients to send the EKG via telephone to a monitoring station when an arrhythmia is felt, or to store the information in the recorder and transmit it later. Doctors can also use high-frequency sound waves (**echocardiography**) to determine the structure and function of the heart. This diagnostic method is often helpful to evaluate for underlying heart disease.

Treatment

Atrial fibrillation and flutter are usually treated with medications and/or electrical shock (**cardioversion**). In some cases, removal of a small portion of the heart (ablation), implantation of a pacemaker or a cardioverter defibrillator, or maze surgery is needed.

If the heart rate cannot be quickly controlled, electrical cardioversion may be used. Cardioversion, the electric shock to the chest wall, is usually performed emergencies. This device briefly suspends the heart's activity and allows it to return to a normal rhythm.

Ablation destroys the heart tissue that causes the arrhythmia. The tissue can be destroyed by catheterization or surgery. Radiofrequency **catheter ablation**, performed in a **cardiac catheterization** laboratory, can cure atrial flutter and control the heart rate in atrial fibrillation. The patient is awake but sedated. A thin tube called a catheter is inserted into a vein and is threaded into the heart. At the end of the catheter, a device maps the electrical pathways of the heart. A cardiologist, a doctor specializing in the heart, uses this map to identify the pathway(s) causing the arrhythmia, and then eliminates it (them) with bursts of high-frequency radio waves. Surgical ablation is performed in an operating room under general **anesthesia**. Computerized mapping techniques are combined with a cold probe to destroy arrhythmia-causing tissue. Ablation is generally successful. When ablation is used for atrial fibrillation, it is usually followed by implantation of a pacemaker as well as drug therapy.

A pacemaker is a battery-powered device about the size of a matchbox that is surgically implanted near the collarbone to regulate the heart beat. Lead wires threaded to the right side of the heart supply electrical energy to pace the atria and ventricles. The **implantable cardioverter defibrillator** is a treatment for serious arrhythmias. The battery-powered device senses an abnormal heart rhythm and automatically provides electrical shock(s). The shock(s) suspends heart activity and then allows the heart to initiate a normal rhythm. Wire electrodes on the device are attached to the heart. Some of the electrodes are attached to the outside of the heart and some are attached to the inside of the heart through veins. The newest implantable cardioverter defibrillators can be implanted in the chest wall and do not require open chest surgery. These devices weigh less than 10 oz. and generally last seven or eight years. An implantable cardioverter defibrillator is usually used with drug therapy, but the amount medication is reduced. In maze surgery, often the last resort, surgeons create a maze of stitches (sutures) that help the heart's electrical impulses travel effectively.

Most of the drugs used for treatment have potential side effects and should be carefully monitored by a doctor. The goal of treatment is to control the rate and rhythm of the heart and to prevent the formation of **blood clots**. If the arrhythmia is caused by heart disease, the heart disease will also be treated. The

American Heart Association recommends aggressive treatment.

A digitalis drug, most commonly **digoxin**, is usually prescribed to control the heart rate. Digitalis drugs slow the heart's electrical impulses, helping to restore the normal rate and rhythm. These drugs also increase the ability of the heart's muscular layer to contract and pump properly. **Beta blockers** and **calcium channel blockers** can also be used for this purpose. Beta blockers slow the speed of electrical impulses through the heart. Some **calcium** channel blockers dampen the heart's response to erratic electrical impulses.

To prevent blood clots, **aspirin** or warfarin (Coumadin) is administered. Warfarin, however, has potential bleeding side effects, especially in older patients. Amiodarone is fairly efffective for atrial flutter. This drug is often able to maintain the heart's proper rhythm and can also help control the heart rate when the flutter occurs.

Prognosis

Patients with atrial fibrillation and flutter can live a normal life for many years as long as the arrhythmia is controlled and serious blood clots are prevented.

Prevention

Atrial fibrillation and flutter can sometimes be prevented when the cause can be identified and controlled. Depending on the cause, prevention could include:

- treating the underlying heart disease
- reducing stress and anxiety
- reducing or stopping consumption of caffeine, alcohol, or tobacco
- discontinuing diet pills or other medications (over-the-counter or prescription)

Atrial flutter *see* **Atrial fibrillation and flutter**

Atrial septal defect

Definition

An atrial septal defect is an abnormal opening in the wall separating the left and right upper chambers (atria) of the heart.

Description

During the normal development of the fetal heart, there is an opening in the wall (the septum) separating the left and right upper chambers of the heart. Normally, this opening closes before birth, but if it does not, the child is born with a hole between the left and right atria. This abnormal opening is called an atrial septal defect and causes blood from the left atrium to flow into the right atrium.

Different types of atrial septal defects can occur, and they are classified according to where in the separating wall they are found. The most commonly found atrial septal defect occurs in the middle of the atrial septum and accounts for about 70% of all atrial septal defects. Abnormal openings can form in the upper and lower parts of the atrial septum as well.

Causes and symptoms

Abnormal openings in the atrial septum occur during fetal development and are twice as common in females as in males. These abnormalities can go unnoticed if the opening is small, producing no abnormal symptoms. If the defect is big, large amounts of blood flowing from the left to the right atrium will cause the right atrium to swell to hold the extra blood.

People born with an atrial septal defect can have no symptoms through their twenties, but by age 40, most people with this condition have symptoms that can include **shortness of breath**, rapid abnormal beating of the atria (**atrial fibrillation**), and eventually **heart failure**.

Diagnosis

Atrial septal defects can be identified by various methods. Abnormal changes in the sound of the heart beats can be heard when a doctor listens to the heart with a stethoscope. In addition, a chest x ray, an electrocardiogram (ECG, an electrical printout of the heartbeats), and an echocardiogram (a test that uses sound waves to form a detailed image of the heart) can also be used to identify this condition.

An atrial septal defect can also be diagnosed by using a test called **cardiac catheterization**. This test involves inserting a very thin tube (catheter) into the

WWW.BOOKBAZ.IR

KEY TERMS

Cardiac catheterization—A test that involves having a tiny tube inserted into the heart through a blood vessel.

Dacron—A synthetic polyester fiber used to surgically repair damaged sections of heart muscle and blood vessel walls.

Echocardiogram—A test that uses sound waves to generate an image of the heart, its valves, and chambers.

heart's chambers to measure the amount of oxygen present in the blood within the heart. If the heart has an opening between the atria, oxygen-rich blood from the left atrium enters the right atrium. Through cardiac catheterization, doctors can detect the higher-than-normal amount of oxygen in the heart's right atrium, right ventricle, and the large blood vessels that carry blood to the lungs, where the blood would normally subsequently get its oxygen.

Treatment

Atrial septal defects often correct themselves without medical treatments by the age of two. If this dose not happen, surgery is done by sewing the hole closed, or by sewing a patch of Dacron material or a piece of the sac that surrounds the heart (the pericardium), over the opening.

Some patients can have the defect fixed by having an clam-shaped plug placed over the opening. This plug is a man-made device that is put in place through a catheter inserted into the heart.

Prognosis

Individuals with small defects can live a normal life, but larger defects require surgical correction. Less than 1% of people younger than 45 years of age die from corrective surgery. Five to ten percent of patients can die from the surgery if they are older than 40 and have other heart-related problems. When an atrial septal defect is corrected within the first 20 years of life, there is an excellent chance for the individual to live normally.

Atrioventricular block *see* **Heart block**
Attapulgite *see* **Antidiarrheal drugs**
Attention deficit disorder *see* **Attention deficit hyperactivity disorder (ADHD)**

Attention deficit hyperactivity disorder (ADHD)

Definition

Attention deficit hyperactivity disorder (ADHD) is a chronic developmental disorder characterized by attention problems, including distractibility, hyperactivity, impulsive behaviors, and the inability to remain focused on tasks or activities. Among its acronyms are AD/HD and ADD. Diagnosed in childhood, the disorder can continue into adulthood.

Demographics

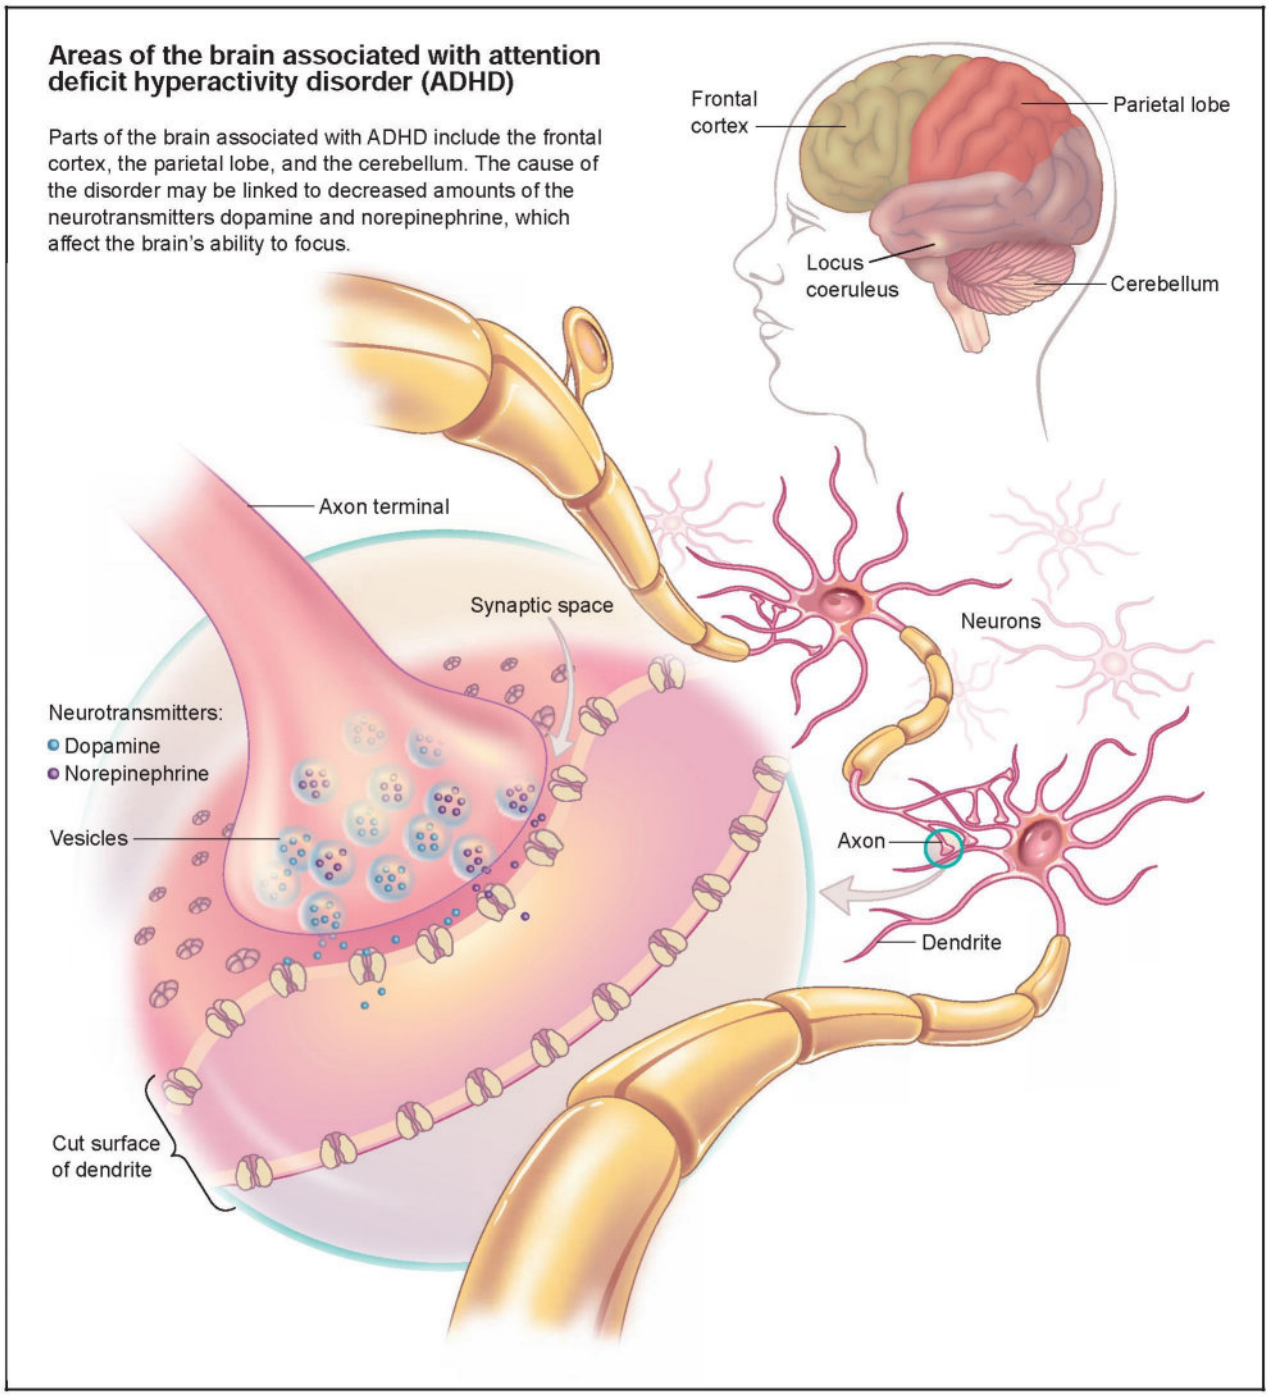
ADHD is a psychiatric disorder that is generally diagnosed in children before the age of 7 years, although its symptoms can continue into adulthood. The Centers for Disease Control and Prevention (CDC) states that about 11% of children from 4 to 17 years of age have been diagnosed in the United States with ADHD. The disorder is more common in boys (13.2%) than in girls (5.6%). In addition, approximately 4.7% of American adults have ADHD.

In the United States, from 2011 through 2012, the average rate of ADHD varied geographically from a low of 5.6% in Nevada, in the western part of the United States, to a high of 18.7% in Kentucky. The CDC also reported that the diagnosis rate of ADHD increased by an average of 3% per year from 1997 to 2006, and from 2003 to 2007, the annual rate was 5.6%. In 2011, the diagnosis rate was 11%.

Worldwide, 3–5% of children are afflicted with ADHD, with rates ranging from less than 1% in the United Kingdom (which has strict standards for diagnosis) to 12% in some countries within South America. Up to 50% of those diagnosed in childhood continue to have symptoms into adulthood.

Description

ADHD, also called hyperkinetic disorder (HKD) outside of the United States, is the most commonly diagnosed neurological disorder in children. It is frequently diagnosed by the age of seven years; however, it can be diagnosed as early as two years. Although



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

childhood ADHD has been studied extensively, less information is available on adult ADHD. Studies on adults have produced a wide range of conflicting results. One reason for the wide range of findings is that the hyperactive component of the disorder often becomes less noticeable as individuals mature and develop more self-control.

Three types of ADHD are recognized by the American Psychiatric Association and outlined in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*). These are:

- predominately hyperactive type, characterized by excessive physical activity (e.g., constant fidgeting, inability to stay seated, inability to engage in quiet

WWW.BOOKBAZ.IR

Drugs used to treat ADHD

Brand name (generic name)	Possible side effects
Adderall (amphetamine and dextroamphetamine)	Dizziness, loss of appetite, nervousness, restlessness
Dexedrine (dextroamphetamine sulfate)	Excessive stimulation, restlessness
Ritalin (methylphenidate hydrochloride)	Insomnia, loss of appetite, nervousness

(Table by PreMediaGlobal. © Cengage Learning®.)

play) and impulsive behaviors (e.g., interrupting, difficulty waiting in line)
- predominately inattentive type, characterized by inability to pay close attention to detail, stay on task, and organize tasks; sometimes referred to as attention deficit disorder (ADD)
- combined hyperactive and inattentive type, characterized by an inappropriately high activity level with a high level of distractibility

Causes and symptoms

Causes

Although the exact causes of ADHD are not known, it is clear that specific parts of the brain are involved, including the frontal cortex, parietal lobe, and possibly the cerebellum. Functional **magnetic resonance imaging** (fMRI) studies comparing the brains of children with ADHD and those without the disorder show that children with ADHD have weaker brain activation of the frontal area when responding to tasks that require inhibition. Researchers believe that this is related to an imbalance in certain neurotransmitters (the chemicals in the brain that carry messages between nerve cells), specifically deficits in the neurotransmitters dopamine and norepinephrine. Drugs used to treat ADHD make dopamine and/or norepinephrine more available in the brain.

ADHD also appears to have a hereditary component. Children with a parent or sibling with ADHD are two to eight times more likely to develop the disorder. Scientists have suggested at least 20 genes that may make a person more vulnerable to ADHD or contribute to the disorder in some way. As of 2011, these genes were being studied to learn more about whether they contribute to ADHD, and, if so, to what degree.

The condition is also more likely in children whose mothers smoke tobacco products, use drugs, or have been exposed to toxins. Pregnant women who smoke tobacco products are at increased risk to giving birth to a child with ADHD. Alcohol or drug use during **pregnancy** may also contribute to increased risk for ADHD. Children who are exposed to toxins are more likely to acquire developmental and behavioral problems associated with ADHD when compared to children who have never been exposed to toxins. One such toxin that has been scientifically shown to produce ADHD-like symptoms is the element lead (symbol Pb), which is sometimes found in paint from old homes and buildings.

A widely publicized study conducted by Benjamin F. Feingold (1899–1982) in the early 1970s suggested that **allergies** to certain foods and food additives caused the characteristic hyperactivity of children with ADHD. Although some children may have adverse reactions to certain foods that can affect their behavior (for example, a rash might temporarily cause a child to be distracted from other tasks), carefully controlled follow-up studies have uncovered no link between **food allergies** and ADHD. Some researchers believe that artificial coloring and food preservatives may contribute to hyperactive behavior as seen in ADHD, but no link has been proven. A popularly held misconception about food and ADHD is that the consumption of sugar causes hyperactive behavior. Studies have shown no link between sugar intake and ADHD. It is important to note, however, that a nutritionally balanced diet is important for normal development in all children.

Symptoms

Children with ADHD have short attention spans, becoming easily distracted or frustrated with tasks. Although they may be quite intelligent, their lack of focus frequently results in poor grades and difficulties in school. Children with ADHD act impulsively, taking action first and thinking later. They are constantly moving, running, climbing, squirming, and fidgeting, but they often have trouble with motor skills and, as a result, may be clumsy and awkward. Their clumsiness may extend to the social arena, where they are sometimes shunned due to their impulsive and intrusive behavior. Because of these symptoms, ADHD children are often troubled by low self-esteem and may have poor relationships.

Diagnosis

There is not a single test for ADHD. Psychiatrists and other mental health professionals use the criteria

listed in the *DSM-5* as a guideline for determining the presence of the disorder. A diagnosis of ADHD requires the presence of at least six of the following symptoms of inattention or six or more symptoms of hyperactivity and impulsivity combined. These symptoms must occur before the age of seven years, be present in at least two different environments (e.g., home and school) for at least six months, and not be attributable to any other developmental or mental health disorder.

Signs of inattention include:

- fails to pay close attention to detail or makes careless mistakes in schoolwork or other activities
- has difficulty sustaining attention in tasks or activities
- does not appear to listen when spoken to
- does not follow through on instructions and does not finish tasks
- has difficulty organizing tasks and activities
- avoids or dislikes tasks that require sustained mental effort (e.g., homework)
- loses things necessary for tasks (e.g., books, tools)
- is easily distracted
- is forgetful in daily activities

Signs of hyperactivity and impulsivity include:

- fidgets with hands or feet or squirms in seat
- does not remain seated or is restless when expected to sit
- runs or climbs excessively when inappropriate (in adolescents and adults, feelings of restlessness)
- has difficulty playing quietly
- blurts out answers before the question has been completed
- has difficulty waiting (e.g., to take turns, to stand in line)
- interrupts and/or intrudes on others

Additional hyperactivity/impulsivity criteria in include:

- acts without thinking, such as starting tasks without reading instructions or speaking without considering the consequences
- is impatient and acts restless when waiting for others
- is uncomfortable doing things slowly, often rushing to complete tasks
- finds it difficult to resist temptations or opportunities, even when they involve risk

Examination

The first step in determining if a child has ADHD is to consult with a pediatrician. The pediatrician can make an initial evaluation of the child's developmental maturity compared to other children in his or her age group. The physician also can perform a comprehensive **physical examination** to rule out any organic causes of ADHD symptoms, such as an overactive thyroid, vision problems, or hearing problems.

If an organic problem is not found, a psychologist, psychiatrist, neurologist, neuropsychologist, or learning specialist typically is consulted to perform a comprehensive ADHD assessment. A complete medical, family, social, psychiatric, and educational history is compiled from existing medical and school records and from interviews with parents and teachers. Interviews may also be conducted with the child, depending on his or her age. Along with these interviews, several clinical inventories may also be used, such as the Conners Rating Scales (Teacher's Questionnaire and Parent's Questionnaire), Child Behavior Checklist (CBCL), and the Barkley Home Situation Questionnaire. These inventories provide valuable information on the child's behavior in different settings and situations. In addition, the Wender Utah Rating Scale has been adapted for use in diagnosing ADHD in adults. Continuous Performance Tests, which involve tasks performed on a computer, may support a diagnosis of attention-deficit type ADHD but by themselves are not diagnostic.

As many as 50% to 60% of people diagnosed with ADHD also meet the diagnostic criteria for another major psychiatric disorder such as **anxiety disorders**, depression, antisocial personality disorder, **oppositional defiant disorder**, **bipolar disorder**, substance abuse disorder, or **conduct disorder**. These individuals also have a high likelihood of having a learning disorder. Children with ADHD also sometimes have **Tourette syndrome**, which is a neurological disorder characterized by vocal tics or compulsive **muscle spasms**. A complete and comprehensive psychiatric assessment is critical to differentiate ADHD from other mood and behavioral disorders.

In the United States, public schools are required by federal law to offer free ADHD assessment upon request. A pediatrician also can provide a referral to a psychologist or pediatric psychiatrist for ADHD assessment. Parents should check with their insurance plans to see if these services are covered.

WWW.BOOKBAZ.IR

Treatment

The CDC reported that in 2007, 2.7 million children from the age of 4 to 17 years were on medication to treat ADHD. It also stated that of all the children diagnosed with ADHD, 66.3% were on medication. Concerning age, the CDC found that children from 11 to 17 years of age were more likely to take medication than children aged 4 to 10 years. In addition, boys were 2.8 times more likely to take medication than were girls. Treatment does not cure ADHD but has been found to help with its symptoms.

Therapy that addresses both psychological and social issues (called psychosocial therapy), usually combined with medications, is the treatment approach of choice to alleviate ADHD symptoms, and in younger children, therapy is preferred over medication. The combination of therapy and medication has proven to be the most effective treatment approach to ADHD. Most children who go through therapy for ADHD develop into normal functioning adults.

Drugs

Stimulant drugs, also known as psychostimulants, are considered the most effective medication for treating ADHD. These drugs generally increase the availability of neurotransmitters in the brain, which tends to reduce such symptoms as inattention, impulsivity, and hyperactivity. Drug therapy must be highly individualized with the benefits balanced against the risk of undesirable side effects. Dextroamphetamine (Dexedrine, Dextrostat), dextroamphetamine/amphetamine mixture (Adderall), methylphenidate (Concerta, Daytrana, Ritalin, Metadate), and dexmethylphenidate (Focalin) are common stimulant drug treatments. These drugs are available in both immediate release and extended release forms.

The use of the stimulant drug pemoline (Cylert) to treat ADHD was stopped in 2005 when the U.S. Food and Drug Administration (FDA) ruled that the risk of liver damage outweighed the benefits of this drug.

Stimulant drugs may have adverse side effects in some children. These side effects include loss of appetite, **insomnia**, mood disturbance, **headache**, and gastrointestinal distress. Tics may also appear and should be monitored carefully. Psychotic reactions are among the more severe side effects. There is some evidence that long-term use of stimulant medication may interfere with physical growth and weight gain. Some experts feel that these effects are ameliorated by taking medication breaks (or drug holidays) over school vacations or weekends. Increasingly, there is concern about long-term use of stimulant medications and their use of in very young children; their use is not recommended in children under age six unless absolutely necessary.

In the past, children who did not respond well to stimulant therapy were often given tricyclic antidepressants such as desipramine (Norpramin, Pertofane) and imipramine (Tofranil). These drugs are now rarely used, as they have a much higher risk of causing serious side effects, including cardiac arrhythmia (irregular heartbeat that can be life threatening).

Nonstimulant drugs are now the preferred choice for treating ADHD when stimulant drugs are found to be ineffective or when adverse side effects occur. Atomoxetine (Strattera) is a nonstimulant norepinephrine reuptake inhibitor. Its effect is to make norepinephrine remain in the brain longer, thus increasing the amount of norepinephrine available.

Other medications used to treat ADHD include some antidepressants (when stimulants or nonstimulants do not work or when a mood disorder is present in addition to ADHD). These include buproprion (Wellbutrin) and venlafaxine (Effexor), both atypical, nontricyclic antidepressants. Clonidine (Catapres) and guanfacine (Intuniv, Tenex), both systemic antihypertensive (blood pressure lowering) medications, also have been used to control aggression and hyperactivity in some ADHD children. They may also reduce symptoms such as tics or insomnia. However, these drugs can have serious side effects if taken with methylphenidate (Ritalin).

Generally, a child's response to medication will change with age and maturation, so ADHD symptoms should be monitored and prescriptions adjusted accordingly.

Therapies

It is important that drug treatment be carefully monitored and not be used exclusively in the management of ADHD. Behavior modification is often used in conjunction with drug therapy. Behavior modification uses a reward system to reinforce good behavior and task completion and can be implemented both in the classroom and at home. A tangible reward such as a sticker may be given to the child every time he or she completes a task or behaves in an acceptable manner. A chart system may be used to display the stickers and visually illustrate the child's progress. When a certain number of stickers are collected, the child may trade them in for a bigger reward such as a trip to the zoo or a day at the beach. The reward system stays in place

until the good behavior becomes ingrained and is sustained without reward.

A variation of this technique, **cognitive-behavioral therapy**, works to decrease impulsive behavior by getting the child to recognize the connection between thoughts and behavior. Behavior is changed by altering negative thinking patterns.

Individual **psychotherapy** may help children with ADHD build self-esteem, give them a place to discuss their worries and anxieties, and help them gain insight into their behavior and feelings. **Family therapy** also may be beneficial in helping family members develop coping skills and in working through feelings of guilt or anger that the parents may be experiencing. Parenting skills training also helps parents to develop methods to better understand and deal with their children.

Social skills training can help children learn more appropriate behaviors while interacting with others. Many support groups are available around the country that help to provide a much needed network of information, education, and other types of support for children and their families.

Alternatives

A number of alternative treatments exist for ADHD. Although there is a lack of controlled studies to prove their efficacy, proponents report that they are successful in controlling symptoms in some ADHD patients. Nevertheless, none of these treatments meets the standards of safety and effectiveness required by conventional medicine. Some of the more popular alternative treatments are:

- EEG (electroencephalograph) biofeedback. By measuring brainwave activity and teaching the ADHD patient which type of brainwave is associated with attention, EEG biofeedback attempts to train patients to generate the desired brainwave activity.
- Dietary therapy. Based in part on the Feingold food allergy diet, dietary therapy focuses on a nutritional plan that is high in protein and complex carbohydrates and free of white sugar and salicylate-containing foods such as strawberries, tomatoes, and grapes. Zinc supplementation has shown positive results in alleviating symptoms of hyperactivity, impulsiveness, and social interaction problems, though additional research is needed.
- Herbal therapy. Herbal therapy uses a variety of natural remedies to address the symptoms of ADHD, such as ginkgo (*Ginkgo biloba*) for memory and mental sharpness and chamomile (*Matricaria recutita*) extract for calming. The safety of herbal remedies has not been demonstrated in controlled studies. For example, it is known that ginkgo may affect blood coagulation, but controlled studies have not yet evaluated the risk of the effect.
- Homeopathic medicine. The theory of homeopathic medicine is to treat the whole person at a core level. Constitutional homeopathic care requires consulting with a well-trained homeopath who has experience working with ADD and ADHD individuals.

Prognosis

Approximately 70% to 80% of ADHD patients treated with stimulant medication experience significant relief from symptoms, at least in the short term. Some children with ADHD seem to outgrow symptoms of the disorder in adolescence or early adulthood, whereas others retain some or all of their symptoms as adults. Some children diagnosed with ADHD also develop a conduct disorder. As many as 25% of adolescents with both ADHD and a conduct disorder go on to develop antisocial personality disorder and the criminal behavior, substance abuse, and high rate of **suicide** attempts that frequently accompany this psychiatric disorder.

Untreated, ADHD negatively affects a child's social and educational performance and can seriously damage his or her sense of self-esteem. Children with ADHD may have impaired relationships with their peers and be looked upon as social outcasts. They may be perceived as slow learners or troublemakers in the classroom. Siblings and even parents may develop resentful feelings toward the child.

Each child should have an individual educational plan (IEP) that outlines modifications to the regular mode of instruction that will facilitate the child's academic performance. Teachers must consider the needs of the child when giving instructions, making sure that they are well paced. They must also understand the origins of impulsive behavior—that the child is not deliberately trying to ruin a lesson or activity by acting unruly. Teachers should teach in a structured way, be comfortable with the remedial services the child may need, and be able to maintain good lines of communication with the parent.

Specialists should devise a series of compensatory strategies that will enable the child to cope with his or her attention deficit or hyperactivity. These strategies might include simple things like creating checklists of things to do before handing in assignments (name on top, check spelling, etc.), putting a clock on the child's desk to help structure time for activities, or covering the pictures on a page until the child has read the words so that he/she is not distracted.

WWW.BOOKBAZ.IR

KEY TERMS

Anxiety disorders—A group of psychological disorders that are all characterized by abnormal fear and/or excessive anxiety.

Bipolar disorder—A mood disorder marked by alternating episodes of extremely low mood (depression) and exuberant highs (mania).

Conduct disorder—A behavioral and emotional disorder of childhood and adolescence. Children with such a disorder act inappropriately, infringe on the rights of others, and violate societal norms.

Dopamine—A neurotransmitter that is involved in many brain activities, including movement and emotion.

Nervous tic—A repetitive, involuntary action, such as the twitching of a muscle or repeated blinking.

Neurotransmitter—One of a group of chemicals secreted by a nerve cell (neuron) to carry a chemical message to another nerve cell, often as a way of transmitting a nerve impulse. Examples of neurotransmitters are acetylcholine, dopamine, serotonin, and norepinephrine.

Norepinephrine—A type of neurotransmitter involved in regulation of concentration, impulse control, judgment, mood, attention span, and psychostimulation.

Oppositional defiant disorder—A disorder characterized by hostile, deliberately argumentative, and defiant behavior toward authority figures.

Tourette syndrome—A neurological disorder characterized by compulsive or vocal tics.

Special assistance may not be limited to educational settings. Families frequently need help in coping with the demands and challenges of ADHD. The symptoms of inattention, shifting activities every five minutes, difficulty completing homework and household tasks, losing things, interrupting, not listening, rule breaking, constant talking, boredom, and irritability can take a toll on any family.

Parents may not understand how attention lapses or impulsivity affect daily functioning, and they might not be trained in the kind of techniques that help children with ADHD manage their behavior. Siblings may be resentful of what the child seems to get away with or the inordinate amount of attention he or she receives. The child with ADHD may be resentful of a younger sibling who is more accomplished at school or never seems to get in any trouble. Family interaction patterns may set up vicious cycles that become destructive and difficult to break.

Support groups for families are increasingly available through school districts and health care providers. Community colleges frequently offer courses in discipline and behavior management. Counseling services are available to complement any types of pharmacological treatment being used. There are a number of popular books available, which are informative and helpful.

Prevention

There is no way to prevent attention deficit hyperactivity disorder. However, it is always wise for pregnant mothers to avoid the use of alcohol, drugs, and tobacco products to avoid medical problems with children later in life.

Audiometry

Definition

Audiometry is the testing of a person's ability to hear various sound frequencies. The test is performed with the use of electronic equipment called an audiometer. This testing is usually administered by a trained technician called an audiologist.

Purpose

Audiometry testing is used to identify and diagnose **hearing loss**. The equipment is used in health screening programs, for example in grade schools, to detect hearing problems in children. It is also used in the doctor's office or hospital audiology department to diagnose hearing problems in children, adults, and the elderly. With correct diagnosis of a person's specific pattern of hearing impairment, the right type of therapy, which might include **hearing aids**, corrective surgery, or **speech therapy**, can be prescribed.

Precautions

Testing with audiometry equipment is simple and painless. No special precautions are required.

An audiologist conducts a hearing test on a young girl. *(© iStockPhoto/Barbara Sauder.)*

WWW.BOOKBAZ.IR

KEY TERMS

Audiogram—A chart or graph of the results of a hearing test conducted with audiographic equipment. The chart reflects the softest (lowest volume) sounds that can be heard at various frequencies or pitches.

Decibel—A unit of measure for expressing the loudness of a sound. Normal speech is typically spoken in the range of about 20-50 decibels.

Otoscope—A hand-held instrument with a tiny light and a funnel-shaped attachment called an ear speculum, which is used to examine the ear canal and eardrum.

Description

A trained audiologist (a specialist in detecting hearing loss) uses an audiometer to conduct audiometry testing. This equipment emits sounds or tones, like musical notes, at various frequencies, or pitches, and at differing volumes or levels of loudness. Testing is usually done in a soundproof testing room.

The person being tested wears a set of headphones that blocks out other distracting sounds and delivers a test tone to one ear at a time. At the sound of a tone, the patient holds up a hand or finger to indicate that the sound is detected. The audiologist lowers the volume and repeats the sound until the patient can no longer detect it. This process is repeated over a wide range of tones or frequencies from very deep, low sounds, like the lowest note played on a tuba, to very high sounds, like the pinging of a triangle. Each ear is tested separately. It is not unusual for levels of sensitivity to sound to differ from one ear to the other.

A second type of audiometry testing uses a headband rather than headphones. The headband is worn with small plastic rectangles that fit behind the ears to conduct sound through the bones of the skull. The patient being tested senses the tones that are transmitted as vibrations through the bones to the inner ear. As with the headphones, the tones are repeated at various frequencies and volumes.

The results of the audiometry test may be recorded on a grid or graph called an audiogram. This graph is generally set up with low frequencies or tones at one end and high ones at the other end, much like a piano keyboard. Low notes are graphed on the left and high notes on the right. The graph also charts the volume of the tones used; from soft, quiet sounds at the top of the chart to loud sounds at the bottom. Hearing is measured in units called decibels. Most of the sounds associated with normal speech patterns are generally spoken in the range of 20-50 decibels. An adult with normal hearing can detect tones between 0-20 decibels.

Speech audiometry is another type of testing that uses a series of simple recorded words spoken at various volumes into headphones worn by the patient being tested. The patient repeats each word back to the audiologist as it is heard. An adult with normal hearing will be able to recognize and repeat 90-100% of the words.

Preparation

The ears may be examined with an otoscope prior to audiometry testing to determine if there are any blockages in the ear canal due to ear wax or other material.

Results

A person with normal hearing will be able to recognize and respond to all of the tone frequencies administered at various volumes in both ears by the audiometry test. An adult with normal hearing can detect a range of low and high pitched sounds that are played as softly as between nearly 0-20 decibels. Normal speech is generally spoken in the range of 20-50 decibels.

Abnormal results

Audiometry test results are considered abnormal if there is a significant or unexplained difference between the levels of sound heard between the two ears, or if the person being tested is unable to hear in the normal range of frequencies and volume. The pattern of responses displayed on the audiogram can be used by the audiologist to identify if a significant hearing loss is present and if the patient might benefit from hearing aids or corrective surgery.

Altha Roberts Edgren

Auditory integration training

Definition

Auditory integration training, or AIT, is one specific type of music/auditory therapy based upon the work of French otolaryngologists Dr. Alfred Tomatis and Dr. Guy Berard.

Origins

The premise upon which most auditory integration programs are based is that distortion in how things are heard contributes to commonly seen behavioral or **learning disorders** in children. Some of these disorders include attention deficit/hyperactive disorder (**ADHD**), **autism**, **dyslexia**, and central auditory processing disorders (CAPD). Training the patient to listen can stimulate central and cortical organization.

Auditory integration is one facet of what audiologists call central auditory processing. The simplest definition of central auditory processing, or CAP, is University of Buffalo professor of audiology Jack Katz's, which is: "What we do with what we hear." Central auditory integration is actually the perception of sound, including the ability to attend to sound, to remember it, retaining it in both the long- and short-term memory, to be able to listen to sound selectively, and to localize it.

Guy Berard developed one of the programs commonly used. Berard's auditory integration training consists of twenty half-hour sessions spent listening to musical sounds via a stereophonic system. The music is random, with filtered frequencies, and the person listens through earphones. These sound waves vibrate and **exercise** structures in the middle ear. This is normally done in sessions twice a day for 10 days.

Alfred Tomatis is also the inventor of the Electronic Ear. This device operates through a series of filters, and reestablishes the dominance of the right ear in hearing. The basis of Tomatis' work is a series of principles that follow:

- The most important purpose of the ear is to adapt sound waves into signals that charge the brain.
- Sound is conducted via both air and bone. It can be considered something that nourishes the nervous system, either stimulating or destimulating it.
- Just as seeing is not the same as looking, hearing is not the same as listening. Hearing is passive. Listening is active.
- A person's ability to listen affects all language development for that person. This process influences every aspect of self-image and social development.
- The capacity to listen can be changed or improved through auditory stimulation using musical and vocal sounds at high frequencies.
- Communication begins in the womb. As early as the beginning of the second trimester, fetuses can hear sounds. These sounds literally cause the brain and nervous system of the baby to develop.

Description

A quartet of CAP defects have been identified that can unfavorably alter how each person processes sound. Among these are:

- Phonetic decoding, a problem that occurs when the brain incorrectly decodes what is being heard. Sounds are unrecognizable, often because the person speaking talks too fast.
- Tolerance-fading memory, a condition with little or poor tolerance for background sounds.
- Auditory integration involves a person's ability to put together things heard with things seen. Characteristically there are long response delays and trouble with phonics, or recognizing the symbols for sounds.
- The fourth problem area, often called auditory organization, overlaps the previous three. It is characterized by disorganization in handling auditory and other information.

Certain audiological tests are carried out to see if the person has a CAP problem, and if so, how severe it is. Other tests give more specific information regarding the nature of the CAP problem. They include:

- Puretone air-conduction threshold testing, which measures peripheral hearing loss. If loss is found, then bone-conduction testing, or evaluation of the vibration of small bones in the inner ear, is also carried out.
- Word discrimination scores (WDS) determines a person's clarity in hearing ideal speech. This is done by presenting 25–50 words at 40 decibels above the person's average sound threshold in each ear. Test scores equal the percentage of words heard correctly.

WWW.BOOKBAZ.IR

ALFRED TOMATIS (1920–2001)

Internationally renowned French otolaryngologist, psychologist, educator and inventor Alfred Tomatis perceived the importance of sound and hearing early in his career. He took his degree as a Doctor of Medicine from the University of Paris and specialized in ear, nose and throat medicine. The son of two opera singers, Tomatis early in his career treated some of his parents' fellow opera singers. From these experiences with the sound of music, he developed the principle that has come to be known as the Tomatis Effect, i.e. that the human voice can only sing what it hears.

Tomatis has been called the Einstein of the ear. It was his research that made the world aware that the ears of an infant in utero are already functioning at four and half months of age. Just as the umbilical cord provides nourishment to the unborn infant's body, Tomatis postulated that the sound of the mother's voice is also a nutrient heard by the fetus. This sound literally charges and stimulates the growth of the brain.

Tomatis took this further, into the realm of language. Tomatis concluded that the need to communicate and to be understood are among our most basic needs. He was a pioneer in perceiving that language problems convert into social problems for people. "Language is what characterizes man and makes him different from other creatures," Tomatis is quoted as saying. The techniques he developed to teach people how to listen effectively are internationally respected tools used in the treatment of autism, attention-deficit disorder, and other learning disabilities.

His listening program, the invention of the Electronic Ear, and his work with the therapeutic use of sound and music for the past fifty years have made Tomatis arguably the best known and most successful ear specialist in the world. There are more than two hundred Tomatis Centers worldwide, treating a vast variety of problems related to the ability to hear. Tomatis died in December of 2001.

- Immittance testing is made up of two parts, assessing the status of, and the protective mechanisms of the middle ear.
- Staggered sporadic word (SSW) testing delivers 40 compound words in an overlapping way at 50 decibels above threshold to each ear of the person being tested. This test provides expanded information that makes it possible to break down CAP problems into the four basic types.
- Speech in noise discrimination (SN) testing is similar to Staggered Sporadic Word testing except that other noise is also added and the percentage correct in quiet is compared with that correct when there is added noise.
- Phonemic synthesis (PS) determines serious learning problems. The types of errors made in sounding out written words or associating written letters with the sounds they represent help in determining the type and severity of CAP problems.

Purpose

Upon completion of an auditory integration training program, the person's hearing should be capable of perceiving all frequencies at, or near, the same level. Total improvement from this therapy, in both hearing and behavior, can take up to one year.

Research and general acceptance

Auditory integration training is based upon newly learned information about the brain. Though brain structures and connections are predetermined, probably by heredity, another factor called *plasticity* also comes into play. Learning, we now know, continues from birth to death. Plasticity is the ability of the brain to actually change its structuring and connections through the process of learning.

Problems with auditory processing are now viewed as having a wide–reaching ripple effect on our society. It is estimated that 30–40% of children starting school have language-learning skills that can be described as poor. CAP difficulties are a factor in several different learning disabilities. They affect not only academic success, but also nearly every aspect of societal difficulties. One example to illustrate this is a 1989 University of Buffalo study where CAP problems were found to be present in a surprising 97% of youth inmates in an upstate New York corrections facility.

Autism

Definition

Autism is a complex developmental disorder distinguished by difficulties with social interaction, verbal and nonverbal communication, and behavioral problems, including repetitive behaviors and narrow focus of interest.

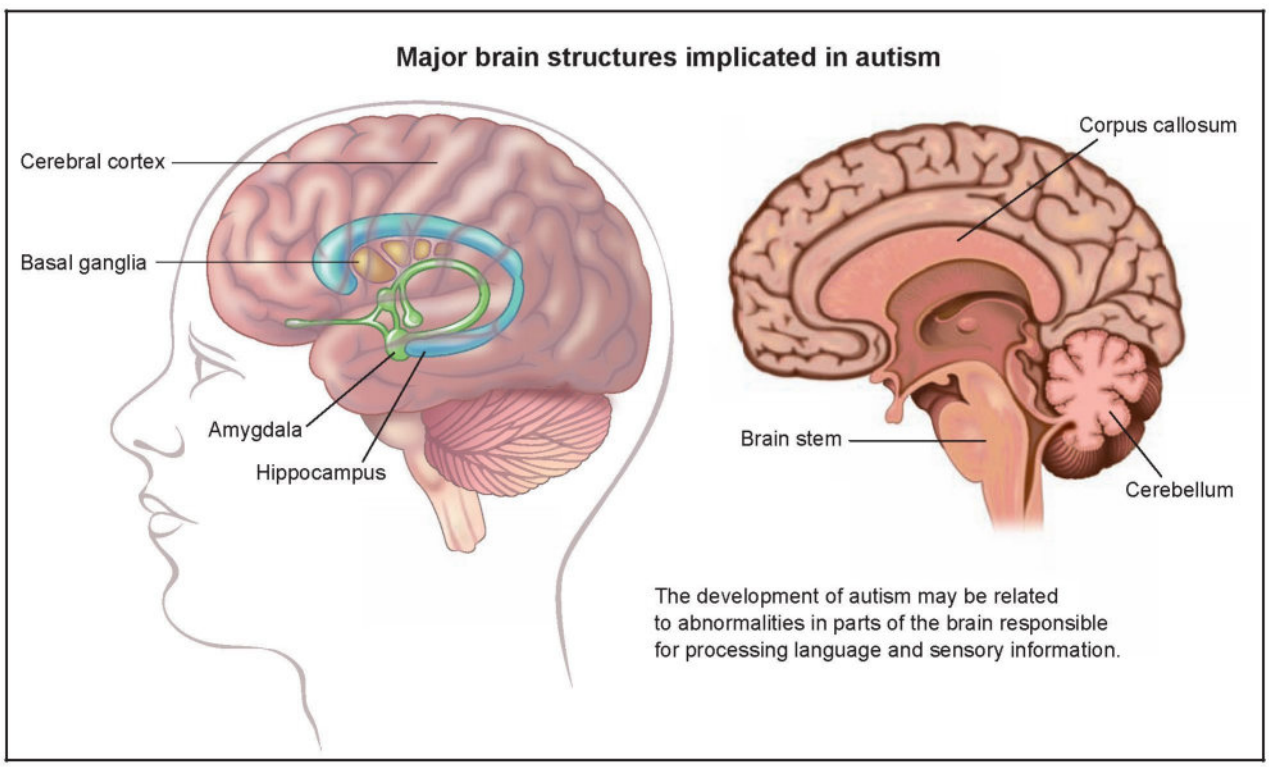
Demographics

Estimates suggest that about 1 of every 110 children in the United States are affected by autism. Autism is almost four times more likely to be diagnosed in males. Autism is a disorder that is found worldwide. In the United Kingdom, one out of every 100 children have autism, with over half a million total diagnosed in the United Kingdom as of 2007. In China, one in every 1,000 children is diagnosed with autism. In India, the rate of incidence is 1 in every 250 children. In Mexico, two to six in every 1,000 children are autistic. Autism is not specific to any one socioeconomic, ethnic, or racial group.

Description

Classic autism is one of several disorders categorized as autism spectrum disorders (ASD). Other ASDs include **Asperger syndrome**, Rett syndrome, childhood disintegrative disorder, and pervasive developmental disorder. In 2010, the classification of autism and autism spectrum disorders was being reevaluated by the American Psychiatric Association for revision in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*). It was been proposed that Asperger syndrome be eliminated as a diagnosis and pervasive developmental disorder not otherwise specified (PPD-NOS) be classified as autism spectrum disorder. This proposal was controversial. When published, *DSM-5* eliminated the categories and created autism spectrum disorders. The three types of symptoms were consolidated into two—social communication impairment and restrictive interests/repetitive behavior.

Autism usually manifests before a child is three years old and it continues throughout his/her lifetime. The severity of the condition varies between individuals, ranging from the most severe (extremely unusual, repetitive, self-injurious, and aggressive behavior) to very mild. No one autistic child is alike in the manifestation of their symptoms so treatment options must be devised to treat each autistic child individually. Autism cannot be cured but is treatable. With early diagnosis and intensive therapy, autistic children may be able to lead healthy, full lives.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

WWW.BOOKBAZ.IR

Prevalence of Autism Spectrum Disorders

- On average, an estimated 1 in 68 children in the United States have an Autism Spectrum Disorder (ASD).
- ASDs occur in all racial, ethnic, and socioeconomic groups, but are on average almost 5 times more likely to occur in boys than in girls.
- Studies in Asia, Europe, and North America have identified a prevalence of ASDs in about 1% of individuals.
- About 1 in 6 children children in the United States had a developmental disability in 2006-2008, ranging from mild speech and language impairments to more severe disorders such as cerebral palsy and autism.

SOURCE: Centers for Disease Control and Prevention, "Autism Spectrum Disorders (ASDs): Data & Statistics." Available onlineat: http://www.cdc.gov/ncbddd/autism/data.html (accessed September 5, 2014).

(Table by PreMediaGlobal. © Cengage Learning®.)

Risk factors

There appears to be a strong genetic basis for autism. Family studies have shown that identical twins are more likely to both be diagnosed with autism than twins who are fraternal (not genetically identical). In a family with one autistic child, the chance of having another child with autism is about one in 20 or approximately 5%, much higher than in the general population.

Other risk factors associated with autism include:

- Gender. Boys are almost four times more likely to be diagnosed with autism than girls.
- Paternal age. Children born of fathers over age 40 have a greater chance of developing autism than children born to younger fathers. The age of the mother appears to have no effect on autism.
- Certain disorders and diseases. Children who have fragile X syndrome, tuberous sclerosis, Tourette syndrome, and epilepsy are more likely to have autism.

Causes and symptoms

Researchers know that autism is a complex brain disorder that affects the way the brain uses or transmits information. Studies have implicated several causes for the disorder including genetic errors and possible environmental triggers, but more investigation is needed. Studies have found abnormalities in several parts of the brain that are believed to have occurred during fetal development. The problem may be centered in the parts of the brain responsible for processing language and information from the senses.

Profound problems with social interaction are the most common symptoms of autism and the most visible. Autistic children have different ways of learning and experiencing the world around them. Often autistic children have more acute reactions to sensory stimulation such as sound and touch. This results in avoidance of eye contact, physical contact, and oftentimes an aversion to music and other sounds. It is perhaps the way autistic children experience their world that causes difficulties with social interaction, language, and nonverbal communication.

Human beings are social and social interaction is present from birth onward. Children with autism have difficulty making social connections. A developmental milestone is when infants can follow an object or person with their gaze. Autistic children tend to avoid eye contact altogether. They do not actively cuddle or hug but rather they passively accept physical contact or they shy away from it. They may become rigid or flaccid when they are held, cry when picked up, and show little interest in human contact. Such children do not lift their arms in anticipation of being picked up. They may appear to have formed no attachment to their parents, and do not learn typical childhood games, such as "peek-a-boo."

Autistic children do not readily learn social cues. They do not know when or how to react to specific social situations or exchanges. Because of this, autistic children tend to look at and respond to different situations similarly. They do not understand that others have different perspectives and, therefore, autistic children seem to lack empathy.

Because of their problems socially and the inability to translate social interactions appropriately, autistic children seem to have uncontrolled emotional outbursts, expressing themselves in a manner that does not suit the specific social situation of the moment.

Language problems

Verbal communication problems vary greatly for autistic children. Some children do not speak at all. Some will only use one or two words at a time. Some autistic children may develop vocabulary only to lose it. Other autistic children may develop an extensive vocabulary; however, they have difficulty sustaining a natural, "back-and-forth" conversation. Autistic children tend to talk in a sing-song voice or more robotically without emotional inflections. Often autistic children do not take body language into consideration and they take what is being said quite literally. Because of their impinged language skills and the inability to express their needs, autistic children seem to act

An autistic student draws a picture while sitting at a table at his school. *(BURGER/PHANIE/Photo Researchers, Inc.)*

inappropriately to get what they need. They may grab something without asking or blurt out statements.

Restricted interests and activity

Language and social problems inhibit social play for autistic children. Autistic children do not engage in imaginative play and role playing. They focus on repetition, some focusing on a subject of interest very intensely.

Autistic children often stick to a rigid daily routine. Any variance to the routine may be upsetting to them and result in an extreme emotional response. Repetitive physical behaviors such as rocking, spinning, and arm flapping are also characteristic of autism. The repetitive behaviors are often self-soothing responses to sensory stimulation from the outside world.

Sensory problems

The sensory world poses a real problem to many autistic children, who seem overwhelmed by their own senses. Children with autism may ignore objects or become obsessed with them, continually watching the object or the movement of their fingers over it. Some children with autism may react to sounds by banging their head or flapping their fingers. Some high-functioning autistic adults who have written books about their childhood experiences report that sounds were often excruciatingly painful to them, forcing them to withdraw from their environment or try to cope by withdrawing into their own world of sensation and movement.

Diagnosis

There is no medical test for diagnosing autism. Diagnosis is made after careful observation and screening by parents, caregivers, and physicians. Early diagnosis is beneficial in treating the symptoms of autism. Some early warning signs are:

- avoiding eye contact
- avoiding physical contact such as hugs
- inability to play make-believe
- not pointing out interesting objects
- not responding to conversation directed at them

WWW.BOOKBAZ.IR

KEY TERMS

Antidepressants—A type of medication that is used to treat depression; it is also sometimes used to treat autism.

Asperger syndrome—Children who have autistic behavior but no problems with language and no clinically significant cognitive delay.

Fragile X syndrome—A genetic condition related to the X chromosome that affects mental, physical and sensory development.

Major tranquilizers—The family of drugs that includes the psychotropic or neuroleptic drugs, sometimes used to help autistic people. They carry significant risk of side effects, including Parkinsonism and movement disorders, and should be prescribed with caution.

Opiate blockers—A type of drug that blocks the effects of natural opiates in the system. This makes some people, including some people with autism, appear more responsive to their environment.

Phenylketonuria (PKU)—An enzyme deficiency present at birth that disrupts metabolism and causes brain damage. This rare inherited defect may be linked to the development of autism.

Rubella—A disease, also known as German measles. When a woman contracts rubella during pregnancy, her developing infant may be damaged. One of the problems that may result is autism.

Stimulants—A class of drugs, including Ritalin, used to treat people with autism. They may make children calmer and better able to concentrate, but they also may limit growth or have other side effects.

Tuberous sclerosis—A genetic disease that causes skin problems, seizures, and intellectual disabilities (ID). Autism occurs more often in individuals with tuberous sclerosis.

- practicing excessively repetitive behaviors
- repeating words or phrases
- losing skills and/or language after learning them

Once parents feel there is a problem or their pediatrician has identified developmental problems during well-baby check-ups, they can seek out a developmental pediatrician for further diagnosis. There are several screening tests used. They are:

- Childhood Autism Rating Scale (CARS)—a test based on a 15 point scale where specific behaviors are observed by the physician.
- Checklist for Autism in Toddlers (CHAT)—a test to detect autism in 18-month olds that utilizes questionnaires filled out by both the parents and the pediatrician.
- Autism Screening Questionnaire—a 40-item questionnaire for diagnosing children four and older.
- Screening Test for Autism in Two-Year-Olds—a direct observation of three skill areas including play, motor imitation, and joint attention.

Some children have a few of the symptoms of autism, but not enough to be diagnosed with the "classical" form of the condition. Children who have autistic behavior but no problems with language may be diagnosed with Asperger syndrome by using the Autism Spectrum Screening Questionnaire, the Australian Scale for Asperger syndrome, or the Childhood Asperger Syndrome Test. The American Psychiatric Association may eliminate the diagnosis of Asperger syndrome in 2012. Children who have no initial symptoms but who begin to show autistic behavior as they get older might be diagnosed with childhood disintegrative disorder (CDD), another autistic spectrum disorder. It is also important to rule out other problems that seem similar to autism.

Treatment

Because the symptoms of autism can vary greatly from one person to the next, there is not a single treatment that works for every person. A spectrum of interventions including behavioral and educational training, diet and **nutrition**, alternative medicine and therapies, and medication should be utilized and fine-tuned to treat the individual. The most strongly recommended treatment option is behavioral and educational training. Early intervention and treatment is key to helping autistic children grow into productive adults.

Educational and behavioral treatment

Several educational and behavioral treatments are:

- Applied Behavior Analysis (ABA)
- speech therapy

- occupational therapy, including sensory integration therapy
- social skills therapy, including play therapy

Typically, behavioral techniques are used to help the child respond and decrease symptoms. This might include positive reinforcement to boost language and social skills. This training includes structured, skill-oriented instruction designed to improve social and language abilities. Training needs to begin as early as possible, since early intervention appears to positively influence brain development.

Most autistic children respond to intervention at home as well as at school. Schools focus on areas where the child may be delayed, such as in speech or socialization. As autistic children grow and move to different phases of childhood and adolescence, parents in collaboration with educators and physicians need to adapt the treatment to best suit the needs of their autistic child.

Medication

No single medication treats symptoms of autism; however, some medications have been used to combat specific needs in autistic children. Drugs can control **epilepsy**, which affects up to 20% of people with autism. Medication can also treat **anxiety**, depression, and hyperactivity. Medication must be individualized and adjusted as the child develops.

Five types of drugs are sometimes prescribed to help the behavior problems of people with autism are:

- stimulants, such as methylphenidate (Ritalin)
- antidepressants, such as fluvoxamine (Luvox)
- opiate blockers, such as naltrexone (ReVia)
- antipsychotics
- tranquilizers

In 2010, news of use of the drug memantine (used in Alzheimer's patients for nearly a decade in the U.S.) being used in a study conducted by Dr. Michael Amen at Ohio State University involving children with autism was reported. The wisdom is, that given their similarities (a malfunction in the brain involving a chemical called glutamate which impacts the patient's speech and interaction), the drug may help in autism, too. Most drugs for autism only focus on lessening symptoms like hyperactivity or repetitive actions. The study was designed to try and help communication, one of the core issues of autism.

Alternatives

Some parents report success with megavitamin therapy. Some studies have shown that vitamin B_6 with magnesium improves eye contact and speech and lessens tantrum behavior. Vitamin B_6 causes fewer side effects than other medications and is considered safe when used in appropriate doses. However, not many health practitioners advocate its use in the treatment of autism, citing that the studies showing its benefit were flawed.

DMG (dimethylglycine)

This compound, available in many health food stores, is legally classified as a food, not a vitamin or drug. Some researchers claim that it improves speech in children with autism. Those who respond to this treatment will usually do so within a week. Again, many doctors do not feel that the studies are adequate to promote this treatment.

Diet

Many parents have seen beneficial effects from a gluten-free and casein-free diet. Gluten is a substance found in the seeds of cereal plants such as wheat, barley, oats, and rye. Casein is a protein found in milk. Often people have sensitivities to these substances without realizing it. Many foods contain these substances as an ingredient; however, there are growing numbers of gluten-free and casein-free foods available for people that would like to eliminate them from their **diets**. Parents interested in using diet as a treatment should discuss with their child's doctor how to initiate an elimination diet.

Exercise

One researcher found that vigorous **exercise** (20 minutes or longer, three or four days a week) seems to decrease hyperactivity, aggression, self-injury and other autistic symptoms.

Prognosis

Autism is treatable but not curable. With appropriate treatments adjusted to suit the autistic child as he/she grows up, the symptoms of autism improve. Today, parents and caregivers are focused on providing the best therapies possible in order for autistic children to develop to their highest potential. Because the incidence of autism seems to be increasing at a rapid rate worldwide, enough so that the CDC has voiced concern about its prevalence, there is more awareness of autism and more ongoing research efforts. People with autism have a normal life expectancy and with proper intervention they can lead full lives.

WWW.BOOKBAZ.IR

Prevention

Until the cause of autism is discovered, prevention is not possible.

Autoimmune disorders

Definition

Autoimmune disorders are conditions in which a person's immune system attacks the body's own cells, causing tissue destruction.

Description

Autoimmunity is accepted as the cause of a wide range of disorders, and it is suspected to be responsible for many more. Autoimmune diseases are classified as either general (systemic), in which the autoimmune reaction takes place simultaneously in a number of tissues, or organ specific, in which the autoimmune reaction targets a single organ. According to the American Autoimmune Related Diseases Association, 50 million Americans have an autoimmune disease. Individuals may, and often do, have more than one autoimmune disorder. Autoimmune diseases are more common in women than in men.

Autoimmune disorders include the following:

- Systemic lupus erythematosus. A general autoimmune disease is one in which antibodies attack a number of different tissues. The disease recurs periodically and is seen mainly in young and middle-aged women.
- Rheumatoid arthritis. Occurs when the immune system attacks and destroys the tissues that line bone joints and cartilage. The disease occurs throughout the body, although some joints may be more affected than others.
- Goodpasture's syndrome. Occurs when antibodies are deposited in the membranes of both the lung and kidneys, causing both inflammation of kidney glomerulus (glomerulonephritis) and lung bleeding. It is typically a disease of young males.
- Grave's disease. Caused by an antibody that binds to specific cells in the thyroid gland, causing them to produce excessive amounts of thyroid hormone.
- Hashimoto's thyroiditis. Caused by an antibody that binds to cells in the thyroid gland. Unlike in Grave's disease, however, this antibody's action results in less thyroid hormone being producing.
- Pemphigus vulgaris. A group of autoimmune disorders that affect the skin.
- Myasthenia gravis. A condition in which the immune system attacks a receptor on the surface of muscle cells, preventing the muscle from receiving nerve impulses and resulting in severe muscle weakness.
- Scleroderma. Also called CREST syndrome or progressive systemic sclerosis, a disease that affects the connective tissue.
- Autoimmune hemolytic anemia. Occurs when the body produces antibodies that target red blood cells.
- Autoimmune thrombocytopenic purpura. Disorder in which the immune system targets and destroys blood platelets.

KEY TERMS

Antibody—A protein normally produced by the immune system to fight infection or rid the body of foreign material. The material that stimulates the production of antibodies is called an antigen. Specific antibodies are produced in response to each different antigen and can only inactivate that particular antigen.

Paresthesia—A prickly, tingling, or burning sensation on the skin.

- Polymyositis and dermatomyositis. Immune disorders that affect the neuromuscular system.
- Pernicious anemia. Disorder in which the immune system attacks the lining of the stomach in such a way that the body cannot metabolize vitamin B_{12}.
- Sjögren's syndrome. Occurs when the exocrine glands are attacked by the immune system, resulting in excessive dryness.
- Ankylosing spondylitis. Immune system induced degeneration of the joints and soft tissue of the spine.
- Vasculitis. A group of autoimmune disorders in which the immune system attacks and destroys blood vessels.
- Type I diabetes mellitus. Appears to be caused by an antibody that attacks and destroys the islet cells of the pancreas, which produce insulin.
- Amyotrophic lateral sclerosis. Also called Lou Gehrig's disease. An immune disorder that causes the death of neurons, which leads to progressive loss of muscular control.
- Guillain-Barre syndrome. Also called infectious polyneuritis. A rare disorder that sometimes occurs after an infection or an immunization, Guillain-Barre syndrome affects the myelin sheath that covers nerve cells. It causes progressive muscle weakness and paralysis.
- Multiple sclerosis. An autoimmune disorder that may involve a virus, it affects the central nervous system, causing loss of coordination and muscle control.
- Celiac disease (sprue). A disease in which the body's reaction to gluten (most commonly found in wheat) causes damage to the intestines that results in poor absorption of nutrients.

Causes and symptoms

To further understand autoimmune disorders, it is helpful to understand the workings of the immune system. The purpose of the immune system is to defend the body against attack by infectious microbes (e.g., bacteria, viruses, fungi) and foreign materials (e.g., chemicals, poisons). When the immune system attacks a foreign invader, it is very specific—a particular immune system cell will only recognize and target one type of invader. To function properly, the immune system must not only develop this specialized knowledge of individual invaders, but it must also learn how to recognize and not destroy cells that belong to the body itself.

Every cell carries protein markers on its surface that identify it in one of two ways: what kind of cell it is (e.g. nerve cell, muscle cell, blood cell, etc.) and to whom that cell belongs. These markers are called major histocompatability complexes (MHCs). When functioning properly, cells of the immune system will not attack any cell with markers identifying it as belonging to the body. Conversely, if the immune system cells do not recognize a cell as "self," they attach themselves to it and put out a signal that the body has been invaded. This in turn stimulates the production of substances such as antibodies that disable and destroy the foreign particles. In case of autoimmune disorders, the immune system cannot distinguish between "self" cells and invader cells. As a result, the same destructive operation is carried out on the body's own cells that would normally be carried out on bacteria, viruses, and other such harmful foreign material.

The reasons why immune systems become dysfunctional and fail to recognize the body's own cells is not well understood. However, most researchers agree that a combination of genetic susceptibility, environmental, and hormonal factors play a role in developing autoimmunity. Researchers also hypothesize that autoimmunity may be triggered by several different mechanisms as follows:

- A substance that is normally sequestered in one part of the body, and therefore not usually exposed to the immune system, is released into the bloodstream where it is attacked.
- The immune system may mistake a component of the body for a similar foreign component.
- Cells of the body may be altered in some way, either by drugs, infection, or other environmental factors, so that they are no longer recognizable as "self" to the immune system.

WWW.BOOKBAZ.IR

- The immune system itself may be damaged, such as by a genetic mutation, and therefore becomes dysfunctional.

The symptoms of autoimmune disorders vary. A short summary of symptoms is as follows: include:

- Systemic lupus erythematosus. Symptoms include fever, chills, fatigue, weight loss, skin rashes (particularly the classic "butterfly" rash on the face), vasculitis, polyarthralgia, patchy hair loss, sores in the mouth or nose, lymph-node enlargement, gastric problems, and, in women, irregular periods. About half of those who experience lupus develop cardiopulmonary problems, and some may develop urinary problems. Lupus can also effect the central nervous system, causing seizures, depression, and psychosis.
- Rheumatoid arthritis. Initially this disorder may be characterized by a low-grade fever, loss of appetite, weight loss, and generalized pain in the joints. The joint pain then becomes more specific, usually beginning in the fingers, then spreading to other areas, such as the wrists, elbows, knees, and ankles. As the disease progresses, joint function diminishes sharply and deformities occur, particularly the characteristic "swan's neck" curling of the fingers.
- Goodpasture's syndrome. Symptoms are similar to that of iron deficiency anemia, including fatigue and pallor. Symptoms involving the lungs may range from a cough that produces bloody sputum to outright hemorrhaging. Symptoms involving the urinary system include blood in the urine and/or swelling.
- Grave's disease. This disease is characterized by an enlarged thyroid gland, weight loss without loss of appetite, sweating, heart palpitations, nervousness, and an inability to tolerate heat.
- Hashimoto's thyroiditis. This disorder generally displays few symptoms.
- Pemphigus vulgaris. This disease is characterized by blisters and deep lesions on the skin.
- Myasthenia gravis. Characterized by fatigue and muscle weakness that at first may be confined to certain muscle groups, but then may progress to the point of paralysis, myasthenia gravis patients often have expressionless faces as well as difficulty chewing and swallowing. If the disease progresses to the respiratory system, artificial respiration may be required.
- Scleroderma. This disorder usually is preceded by Raynaud's phenomenon. Symptoms that follow include pain, swelling, and stiffness of the joints, and the skin takes on a tight, shiny appearance. The digestive system also becomes involved, resulting in weight loss, appetite loss, diarrhea, constipation, and distention of the abdomen. As the disease progresses, the heart, lungs, and kidneys become involved, and malignant hypertension (high blood pressure) causes death in approximately 30% of cases.
- Autoimmune hemolytic anemia. May be acute or chronic. Symptoms include fatigue and abdominal tenderness due to an enlarged spleen.
- Autoimmune thrombocytopenic purpura. Characterized by pinhead-size red dots on the skin, unexplained bruises, bleeding from the nose and gums, and blood in the stool.
- Polymyositis and dermatomyositis. In polymyositis, symptoms include muscle weakness, particularly in the shoulders or pelvis, which prevents the patient from performing everyday activities. In dermatomyositis, the same muscle weakness is accompanied by a rash that appears on the upper body, arms, and fingertips. A rash may also appear on the eyelids, and the area around the eyes may become swollen.
- Pernicious anemia. Signs of pernicious anemia include weakness, sore tongue, bleeding gums, and tingling in the extremities. Because the disease causes a decrease in stomach acid, nausea, vomiting, loss of appetite, weight loss, diarrhea, and constipation are possible. Also, because vitamin B_{12} is essential for the nervous system function, its deficiency brought about by the disease can result in a host of neurological problems, including weakness, lack of coordination, blurred vision, loss of fine motor skills, loss of the sense of taste, ringing in the ears, and loss of bladder control.
- Sjögren's syndrome. Characterized by excessive dryness of the mouth and eyes.
- Ankylosing spondylitis. Generally begins with lower back pain that progresses up the spine. The pain may eventually become crippling.
- Vasculitis. Symptoms depend upon the group of veins affected and can vary greatly.
- Type I diabetes mellitus. Characterized by fatigue and an the inability to break down glucose, resulting in abnormally high level of glucose in the blood (hyperglycemia).
- Amyotrophic lateral sclerosis. First signs are stumbling and difficulty climbing stairs. Later, muscle cramps and twitching may be observed as well as weakness in the hands making fastening buttons or turning a key difficult. Speech may become slowed or

slurred. There may also be difficulty swallowing. As respiratory muscles atrophy, there is increased danger of aspiration or lung infection.

- Guillain-Barre syndrome. Muscle weakness in the legs occurs first, then the arms and face. Paresthesia is often present. This disorder affects both sides of the body and may involve paralysis of the muscles that control breathing.
- Multiple sclerosis. Like amyotrophic lateral sclerosis, the first symptom may be clumsiness. Weakness or exhaustion is often reported, as well as blurry or double vision. The individual may experience dizziness, depression, loss of bladder control, and muscle weakness so severe that the patient is confined to a wheelchair.
- Celiac disease. Damage to the lining of the small intestine causes immediate difficulties in digesting food that result in diarrhea, gas, and cramps, and long-term symptoms of vitamin and mineral deficiencies, anemia, osteoporosis, and weight loss.

Diagnosis

A variety of tests are involved in the diagnosis of autoimmune disorders, depending on the particular disease such as blood tests, **cerebrospinal fluid analysis**, electromyogram (measures muscle function), and **magnetic resonance imaging** of the brain. Usually, these tests determine the location and extent of damage or involvement. They also are useful in charting progress of the disease and as baselines for treatment.

The principle tool, however, for authenticating autoimmune disease is antibody testing. Such tests involve measuring the level of antibodies found in the blood and determining if they react with specific antigens (protein triggers) that would give rise to an autoimmune reaction. An elevated amount of antibodies indicates that a general immune reaction is occurring. Since elevated antibody levels also are seen in common infections, infections must be ruled out as the cause for the increased antibody levels.

Antibodies can also be typed by class. There are five classes of antibodies, and they can be separated in the laboratory. The class IgG is usually associated with autoimmune diseases. Unfortunately, IgG class antibodies are also the main class of antibody seen in normal immune responses.

The most useful antibody tests involve introducing the patient's antibodies to samples of his or her own tissue, usually thyroid, stomach, liver, and kidney tissue. If antibodies bind to the "self" tissue, this is diagnostic for an autoimmune disorder. Antibodies from a person without an autoimmune disorder would not react to "self" tissue.

Treatment

Treatment of autoimmune diseases is specific to the disease, and usually focuses on alleviating or preventing symptoms rather than correcting the underlying cause. For example, if a gland involved in an autoimmune reaction is not producing a hormone, for example insulin, administration of that hormone is required. Administration of a hormone, however, will not restore the function of the gland damaged by the autoimmune disease.

The other aspect of treatment is controlling the inflammatory and proliferative nature of the immune response. This generally is accomplished with two types of drugs. Corticosteroid compounds (e.g., prednisone) are used to control inflammation. There are many different **corticosteroids**, each having undesirable side effects, especially with long-term use.

The proliferative nature of the immune response is controlled with immunosuppressive drugs (e.g., azathioprine, chlorambucil, cyclophosphamide, methotrexate). These drugs work by inhibiting the replication of cells and, therefore also suppress non-immune cells, leading to side effects such as anemia (too few red blood cells). In addition, other drugs may be used to treat symptoms of specific disorders.

Another approach is the use of drugs such as entanercept (Enbrel), imflixmab (Remicade), and adalimumab (Humira) that block the action of **tumor necrosis factor** (TNF). TNF is a substance that can cause inflammation in the body. These drugs have proved very effective in relieving symptoms in people with **rheumatoid arthritis**. However, in June 2008, the United States Food and Drug Administration (FDA) began investigating whether these drugs, especially when administered long term to younger patients, caused an increase in cancer, especially lymphoma (cancer of the lymph tissue). As of 2009, the data on potential cancer risks related to these drugs was confusing and difficult to assess because many patients who developed cancer were taking other drugs in addition to TNFs.

Prognosis

Prognosis depends upon the pathology of each autoimmune disease.

WWW.BOOKBAZ.IR

Prevention

Though the mechanisms involved in how these diseases affect the body are known, it is still unclear why the body turns on itself, thus most autoimmune disorders cannot be prevented. Since more women than men are affected by some of these disorders (e.g., lupus), some researchers are looking into hormones as a factor that may be controlled to prevent or slow certain autoimmune disorders. This, **gene therapy**, and drugs that target specific immune system cells may help prevent or treat autoimmune disorders in the future.

Autopsy

Definition

An autopsy is a postmortem assessment or examination of a body to determine the cause of death. An autopsy is performed by a physician trained in pathology.

Purpose

Most autopsies advance medical knowledge and provide evidence for legal action. Medically, autopsies determine the exact cause and circumstances of death, discover the pathway of a disease, and provide valuable information to be used in the care of the living. When foul play is suspected, a government coroner or medical examiner performs autopsies for legal use. This branch of medical study is called **forensic medicine**. Forensic specialists investigate deaths resulting from violence or occurring under suspicious circumstances.

Benefits of research from autopsies include the production of new medical information on diseases such as **toxic shock syndrome**, acquired **immunodeficiency** syndrome (**AIDS**). **Organ donation**, which can potentially save the lives of other patients, is also another benefit of autopsies.

Precautions

When performed for medical reasons, autopsies require formal permission from family members or the legal guardian. (Autopsies required for legal reasons when foul play is suspected do not need the consent of next of kin.) During the autopsy, very concise notes and documentation must be made for both medical and legal reasons. Some religious groups prohibit autopsies.

Description

An autopsy can be described as the examination of a deceased human body with a detailed exam of the person's remains. This procedure dates back to the Roman era when few human dissections were performed; autopsies were utilized, however, to determine the cause of death in criminal cases. At the beginning of the procedure the exterior body is examined and then the internal organs are removed and studied. Some pathologists argue that more autopsies are performed than necessary. However, recent studies show that autopsies can detect major findings about a person's condition that were not suspected when the person was alive. And the growing awareness of the influence of genetic factors in disease has also emphasized the importance of autopsies.

Despite the usefulness of autopsies, fewer autopsies have been performed in the United States since 2000. A possible reason for this decline is concern about malpractice suits on the part of the treating physician. Hospitals may be performing fewer autopsies because of the expense or because modern technology, such

KEY TERMS

Acquired immunodeficiency syndrome (AIDS)—A group of diseases resulting from infection with the human immunodeficiency virus (HIV). A person infected with HIV gradually loses immune function, becoming less able to resist aliments and cancers, resulting in eventual death.

Computed tomography scan (CT scan)—The technique used in diagnostic studies of internal bodily structures in the detection of tumors or brain aneurysms. This diagnostic test consists of a computer analysis of a series of cross-sectional scans made along a single axis of a bodily structure or tissue that is used to construct a three-dimensional image of that structure.

Creutzfeld-Jakob disease—A rare, often fatal disease of the brain, characterized by gradual dementia and loss of muscle control that occurs most often in middle age and is caused by a slow virus.

Hepatitis—Inflammation of the liver, caused by infectious or toxic agents and characterized by jaundice, fever, liver enlargement, and abdominal pain.

Magnetic resonance imaging (MRI)—A diagnostic tool that utilizes nuclear magnetic energy in the production of images of specific atoms and molecular structures in solids, especially human cells, tissues, and organs.

as CT scans and **magnetic resonance imaging**, can often provide sufficient diagnostic information. Nonetheless, federal regulators and pathology groups have begun to establish new guidelines designed to increase the number and quality of autopsies being performed.

Many experts are concerned that if the number of autopsies increases, hospitals may be forced to charge families a fee for the procedure as autopies are not normally covered by insurance companies or Medicare. Yet, according to several pathologists, the benefit of the procedure for families and doctors does justify the cost. In medical autopsies, physicians remain cautious to examine only as much of the body as permitted according to the wishes of the family. It is important to note that autopsies can also provide peace of mind for the bereaved family in certain situations.

Preparation

If a medical autopsy is being performed, written permission is secured from the family of the deceased

Aftercare

Once the autopsy has been completed, the body is prepared for final arrangements according to the family's wishes

Risks

There are some risks of disease transmission from the deceased. In fact, some physicans may refuse to do autopsies on specific patients because of a fear of contracting diseases such as AIDS, hepatitis, or Creutzfeld-Jakob disease.

Results

In most situations the cause of death is determined from the procedure of an autopsy without any transmission of disease.

Abnormal results would include inconclusive results from the autopsy and transmission of **infectious disease** during the autopsy.

Avian flu

Definition

Avian **influenza**, known more casually as bird flu, is an **infectious disease** caused by a family of viruses that normally infect birds. Beginning in 1997, a subtype of avian influenza known as Avian influenza A (H5N1), has infected and caused a small number of deaths in humans.

WWW.BOOKBAZ.IR

Demographics

The avian H5N1 influenza virus was first isolated in terns (migratory shore birds) in South Africa in 1961. The virus is highly contagious and sometimes fatal in birds; it did not appear to cause disease in humans until 1997. In that year in Hong Kong, H5N1 bird flu caused 18 confirmed cases of severe respiratory disease in humans, of which six were fatal. All but one of the individuals diagnosed with bird flu in Hong Kong had close contact with infected poultry. The exception was a case in which the disease was transmitted from child to parent but spread no further.

As of October 2014, there were 668 laboratory-confirmed cases of H5N1 avian influenza in humans. Of these, 393 were fatal. The disease can affect people of all ages, genders, and ethnicities. Almost all individuals who have developed avian flu were in close contact with infected birds; only a few contracted the disease from extended contact with a sick family member.

Description

There are three types of influenza viruses called types A, B, and C. Only influenza A viruses causes serious, widespread illness in humans. Several different strains or subtypes of influenza A virus cause infection in humans. Other subtypes of influenza A cause disease in birds, pigs, horses, ferrets, whales, and seals. In most cases, the subtypes that cause disease in one species do not spread the disease to other species.

Bird flu was first identified in Italy more than 100 years ago. Avian influenza viruses can infect both domestic and wild birds including chickens, ducks, geese, turkeys, swans, pheasants, and quail. Although the disease is often fatal in domestic birds (e.g., chickens, turkeys), it often causes less severe illness in wild birds; wild ducks are natural reservoirs of infection. Infected wild birds shed large quantities of virus in their feces, but often appear to be relatively unaffected by flu symptoms. During migration, infected wild birds encounter other wild and domestic birds, such as chickens, and spread the disease to them. The virus then kills a large percentage of domestic birds, along with some species of wild birds. There are several subtypes of avian influenza virus, but the one of most concern to human health is called H5N1. Under most circumstances avian influenza viruses do not infect humans.

Understanding the avian influenza virus

Influenza viruses are protein sacks with a core of eight loosely connected genes. Two proteins spike up from the surface of the virus. The most plentiful protein is called haemagglutinin (H). The other surface protein is neuraminidase (N). The job of these proteins is to hook the influenza virus on to the surface of a cell in the animal it has infected and then help get the virus's genes inside that cell. Once inside, the virus genes take over the host cell and reprogram it to make thousands of copies of the virus.

There are many subtypes of influenza A viruses. These are identified by a series of letters and numbers that refer to two surface proteins, H and N. There are 16 known types of H proteins and nine known types of N proteins of influenza The structure of the genes in the influenza virus allows these viruses to mutate (change) very rapidly. Many combinations of the two proteins can result from these mutations, each representing a new subtype of influenza A.

According to the United States Centers for Disease Control and Prevention (CDC) 15 different influenza A subtypes can infect birds. Normally the subtypes of influenza that infect birds do not harm human, although some can infect pigs. However, the avian influenza virus called H5N1 has mutated in such a way that it is able to infect humans.

Humans and bird flu

When H5N1 avian flu was first discovered to infect humans in Hong Kong in 1997, it was feared that the disease, now called bird flu, would sweep through the community and kill thousands the way another subtype of influenza had swept across the world in 1918 and 1919. That influenza pandemic killed between 20 and 100 million people on six continents. To prevent this, Hong Kong health authorities had ordered all poultry be killed. Within three days, about 1.5 million birds in Hong Kong were destroyed to prevent further spread of the disease. Hong Kong, a relatively small island, was able to contain the infection.

The next outbreak of avian flu in humans was reported in Asia. From November 2003 through March 2004, a few human cases of bird flu were found in China, Vietnam, and Thailand. Meanwhile avian flu was epidemic among the bird populations in Japan, Thailand, Lao People's Democratic Republic (formerly Laos), China, and Indonesia. Millions of birds died from avian flu as the disease spread throughout Southeast Asia, and many of these countries reported a small number of human infections. By

2009, the disease had spread to some parts of the Middle East and Northern Africa, where Egypt and Djibouti reported some human cases. As of mid-2009, more than three-quarters of all laboratory-confirmed cases of avian flu in humans had occurred in Southeast Asia; none had been reported in North or South America, or Australia.

Risk factors

People at greatest risk of contracting avian flu are those who live or work closely with poultry. Potentially vulnerable people included those working on poultry on farms, in poultry processing plants, and live bird markets. Individuals living with a family member who has avian flu are also at risk of developing the disease. Avian flu does not spread easily to humans, and many people who are exposed to infected birds do not get sick.

Causes and symptoms

An influenza virus that birds carry in their intestines causes Avian flu. The virus spreads as infected birds excrete saliva, nasal secretions, and feces. Birds vulnerable to the flu become infected when they come into contact with the excretions or surfaces contaminated by the viruses.

Birds that survive the H5N1 infection can excrete the virus for at least 10 days. This allows the H5N1 strain to spread through bird-to-bird contact from wild birds to domestic birds on farms and in live bird markets. The virus can also spread in surfaces including manure, bird feed, equipment, vehicles, egg flats, and crates, and the clothing and shoes of people who are exposed to the virus. Influenza is a respiratory disease. People must inhale the virus or carry it on their hands to their nose, eyes, or mouth to become sick. People cannot get the disease by eating properly cooked poultry.

In general, people who contract bird flu have symptoms similar to seasonal human influenza including **fever**, **cough**, **sore throat**, and aching muscles. Other symptoms included eye infections (**conjunctivitis**), **pneumonia**, acute respiratory distress, and viral pneumonia. Influenza weakens the respiratory system and leaves the lungs more vulnerable to infection. Many people with flu die from pneumonia caused by a secondary bacterial infection. Bacteria are able to grow in the lungs because the body's defenses have been weakened by the flu virus.

Diagnosis

The symptoms of avian flu and human flu are very similar. A physician may suspect avian influenza if an individual showing flu-like symptoms has been in close contact with poultry in an infected area. Nevertheless, laboratory testing is needed to confirm a diagnosis of avian influenza. Symptoms normally develop within 7 days of infection.

KEY TERMS

Pandemic—The occurrence of a disease that in a short time infects a large percentage of the population over a wide geographical area.

Secondary or opportunistic infection—An infection by a microbe that occurs because the body is weakened by a primary infection caused by a different kind of microbe.

Tests

Diagnostic tests for human flu are rapid and reliable, according to the World Health Organization (WHO). International laboratories within WHO's global network have high-security facilities and experienced staff to test samples of suspected avian flu sent from around the world. Test methods include a viral culture that analyzes a blood sample and swabbings from the nose or throat. Other testing can be done on respiratory secretions.

In April 2009, the United States Food and Drug Administration (FDA) approved a rapid detection test for the H5N1 strain of bird flu. The test is manufactured by Arbor Vita Corporation of California. All it requires is a swab from the nose or throat of an ill individual. This new test produces results in about 40 minutes. Previous bird flu tests took at minimum four hours to complete.

Treatment

Drugs

Some anti-viral drugs appear to be partially effective against avian flu viruses if they are administered promptly, usually within 48 hours after the start of symptoms. These drugs do not cure flu, but lessen its symptoms and duration. In the United States, four drugs have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of influenza A viruses in otherwise healthy adults. These are amantadine (Symmetrel), rimantadine (Flumadine), oseltamivir (Tamiflu), and zanamivir (Relenza). Research indicates that the avian H5N1 virus is resistant to amantadine and rimantadine,

WWW.BOOKBAZ.IR

therefore, the drugs of choice for treating bird flu are oseltamivir and zanamivir.

Antibiotics may be needed to treat secondary bacterial infections. **Acetaminophen** may be used to control fever and reduce aches.

Alternatives

In March of 2005, people in South Korea began eating more kimchi to ward off avian flu infection, according to the reports from the British Broadcasting Company and other news organizations. The public turned to the spicy vegetable dish after scientists at Seoul National University announced that kimchi aided in the recovery of 11 out of 13 infected chickens. The scientists fed the birds an extract of kimchi, a dish made by fermenting cabbage with red peppers, radishes, and large amounts of garlic and ginger. A week later, all but two birds showed signs of recovery. The researchers acknowledged that their study was unscientific. At that time, they were not sure how or why kimchi was related to the recovery. However, the announcement led people to again regard kimchi as a health remedy.

Home remedies

Much of the treatment for influenza is supportive and consists bed rest, drinking plenty of fluids to stay hydrated, and using a humidifier to relieve nasal congestion and ease breathing.

Prognosis

About 60% of individuals who develop avian influenza die. The rest normally recover completely.

Prevention

Although avian influenza has been confirmed in 668 individuals worldwide, scientists at WHO, the CDC, and **public health** agencies of many other countries are concerned about the deadly consequences that could occur if H5N1 mutated into a virus subtype that could spread easily from one human to another. A strain of bird flu spread by human-to-human contact could cause an influenza pandemic and sicken millions. WHO and CDC experts believe that the question is not if another influenza epidemic will occur, but when it will happen and how severe it will be. For this reason, prevention strategies and pandemic planning are extremely important.

In the United States, the CDC is among the organizations preparing for a possible outbreak of bird flu in humans. In addition to laboratories equipped to test for bird flu, the CDC recommends precautions to prevent the spread of flu and other respiratory infections. Precautionary measures include restricting bird from coming into the United States from infected countries, testing poultry for avian flu viruses, and euthanizing infected birds. People with symptoms of respiratory infection are advised to cover their mouths or use facial tissues when coughing or sneezing. After coughing or sneezing, individuals should wash their hands well with soap and water, alcohol-based hand rub, or antiseptic handwash.

As of 2014, bird flu was primarily a risk for people in infected areas who work with poultry. People working with birds in locations such as commercial poultry facilities, veterinary offices, and live bird markets should wear protective clothing. That equipment includes boots, coveralls, face masks, gloves, and headgear, according to the United States Department of Agriculture (USDA).

Furthermore, poultry producers should implement security measures to prevent the outbreak of a highly pathogenic virus. Those actions include keeping flocks away from wild or migratory birds and providing clothing and disinfectant facilities for employees. Plastic crates are recommended for use at live bird markets because they are easier to clean than wood crates. Cleaning and disinfecting areas are also important for preventing an outbreak. Infected birds must be quarantined or destroyed.

In July 2007, the United States Food and Drug Administration approved the first vaccine for use against H5N1 bird flu. In addition, many governments around the world have stockpiled antiviral medications that can rapidly be made available should a serious influenza outbreak occur.

Aviation medicine

Definition

Also known as aerospace medicine, flight medicine, or space medicine, aviation medicine is a medical specialty that focuses on the physical and psychological conditions associated with flying and space travel.

Purpose

Since flying airplanes and spacecraft involves great risk and physical demands, such as changes in gravity and oxygen, pilots and astronauts need medical experts to protect their safety and the public's safety.

Description

Pressure changes

In the United States, the Federal Aviation Administration (FAA) requires all pilots who fly above 14,500 ft. (4,420 m) to be prepared for pressure changes caused by lower oxygen levels at high altitude. Pilots must either have a pressurized cabin or access to an oxygen mask. Without these protections, they could experience hypoxia, or **altitude sickness**. Hypoxia reduces the amount of oxygen in the brain, causing such symptoms as **dizziness**, **shortness of breath**, and mental confusion. These symptoms could cause the pilot to lose control of the plane. Hypoxia can be treated with **oxygen therapy**.

Rapid altitude increases and decreases can cause **pain** because there is an air pocket in the middle portion of the ear. To equalize pressure in the ear, physicians typically advise pilots and passengers to clear their sinuses by plugging their nose and blowing until the eardrums pop. Other options include yawning, swallowing or chewing gum. For people with a cold or a severely blocked middle ear, the use of **decongestants**, **antihistamines**, or nasal sprays may help. Without taking steps to equalize pressure, the tympanic membrane could rupture, causing **hearing loss**, vertigo, dizziness, and nausea.

Gravity's impact

Fighter pilots who fly high-performance jets can experience health problems during rapid acceleration and when executing tight turns at high speed. During these moves, a pilot experiences extreme gravity conditions that can pull blood away from the brain and heart and into the lower body. This can cause the pilot to have tunnel vision or pass out. To prevent these potentially deadly situations, the military requires fighter pilots to wear special flight suits, or G suits, which have compartments that fill with air or fluid to keep blood from pooling in the lower body.

Some pilots, like the Blue Angels, use a technique called the **Valsalva Maneuver** instead of G suits to prevent black outs during high-performance flying. The Valsalva Maneuver involves grunting and tightening the abdominal muscles to stop blood from collecting in the wrong parts of the body.

PREVENTIVE CARE. Since any routine health problem that affects a pilot could mean the loss of hundreds of lives, aviation medicine specialists who work for commercial airlines and the military take special care to educate pilots about proper diet, **exercise** and preventive health tools. For example, physicians may frequently screen pilots for vision changes caused by **glaucoma** or **cataracts**. They also will check for hearing loss and encourage the pilot to wear earplugs or headphones to buffer engine noise. To monitor for **heart disease**, physicians will check blood pressure and may order diagnostic tests such as an ECG or **stress test**.

Motion sickness

Many people experience nausea, vertigo, and disorientation when they first arrive in space. This is caused by changes in the fluid in the inner ear, which is sensitive to gravity and affects our sense of spatial orientation. The symptoms typically ease

WWW.BOOKBAZ.IR

KEY TERMS

G suits—Special flight suits, worn by fighter pilots, which have compartments that fill with air or fluid to keep blood from pooling in the lower body during rapid acceleration and tight turns.

Hypoxia—Also called altitude sickness, a condition that reduces the amount of oxygen in the brain causing such symptoms as dizziness, shortness of breath, and mental confusion.

Tympanic membrane—A structure in the middle ear that can rupture if pressure in the ear is not equalized during airplane ascents and descents.

Valsalva Maneuver—Contraction of abdominal muscles of pilots to prevent black outs during high-performance flying.

after several days, but often recur when the astronaut returns to Earth. To treat this condition, physicians give astronauts **motion sickness** medication, such as lorazepam.

Bone and muscle loss

In zero-gravity conditions, astronauts lose bone and muscle mass. On earth, the natural resistance of gravity helps build stronger muscles and bones during normal weight-bearing activities like walking or even sitting at a desk. In space, however, astronauts must work harder to prevent bone and muscle loss. Exercise is an important treatment. Crew members may use an exercise cycle or resistive rubber bands to stay in shape. Physicians also may give them medication to prevent bone loss and prescribe **nutritional supplements**, such as a mixture of essential amino acids and carbohydrates, to limit muscle atrophy.

Radiation

Another health threat to space travelers is radiation. Harmful rays can alter the DNA in human cells and cause cancer. Excess radiation also can weaken the immune system. To prevent these problems, physicians may give astronauts nutritional supplements. For example, research has show that n-3 fatty acids found in fish oil reduce DNA damage.

Cardiovascular issues

When astronauts return to earth after a long mission, they tend to feel dizzy and black out. Scientists are concerned about this dilemma because it could be dangerous if the crew members need to make an emergency exit. One way to prevent this problem, which is caused by a drop in blood pressure, is to have the astronauts drink extra fluids and increase salt intake to increase blood volume. Physicians also may prescribe medication that causes blood vessels to contract. As another precaution, astronauts also put on protective flight suits, or G suits, before they re-enter the earth's atmosphere.

Ayurvedic medicine

Definition

Ayurvedic medicine is a system of healing that originated in ancient India. In Sanskrit, *ayur* means

Ayurvedic body types (doshas)

	Vata	Pitta	Kapha
Physical characteristics	Thin Prominent features Cool, dry skin Constipation Cramps	Average build Fair, thin hair Warm, moist skin Ulcers, heartburn, and hemorrhoids Acne	Large build Wavy, thick hair Pale, cool, oily skin Obesity, allergies, and sinus problems High cholesterol
Emotional characteristics	Moody Vivacious Imaginative Enthusiastic Intuitive	Intense Quick tempered Intelligent Loving Articulate	Relaxed Not easily angered Affectionate Tolerant Compassionate
Behavioral characteristics	Unscheduled sleep and meal times Nervous disorders Anxious	Orderly Structured sleep and meal times Perfectionist	Slow, graceful Long sleeper and slow eater Procrastinator

(Table by PreMediaGlobal. © Cengage Learning®.)

life or living, and *veda* means knowledge, so Ayurveda has been defined as the "knowledge of living" or the "science of longevity." Ayurvedic medicine utilizes diet, **detoxification** and purification techniques, herbal and mineral remedies, **yoga**, breathing exercises, **meditation**, and **massage therapy** as holistic healing methods. Ayurvedic medicine is widely practiced in modern India and has been steadily gaining followers in the West.

Purpose

According to the original texts, the goal of Ayurveda is prevention as well as promotion of the body's own capacity for maintenance and balance. Ayurvedic treatment is non-invasive and non-toxic, so it can be used safely as an alternative therapy or alongside conventional therapies. Ayurvedic physicians claim that their methods can also help stress-related, metabolic, and chronic conditions. Ayurveda has been used to treat **acne**, **allergies**, **asthma**, **anxiety**, arthritis, **chronic fatigue syndrome**, colds, **colitis**, **constipation**, depression, diabetes, flu, **heart disease**, **hypertension**, immune problems, inflammation, **insomnia**, nervous disorders, **obesity**, skin problems, and **ulcers**.

Ayurvedic physicians seek to discover the roots of a disease before it gets so advanced that more radical treatments are necessary. Thus, Ayurveda seems to be limited in treating severely advanced conditions, traumatic injuries, acute **pain**, and conditions and injuries requiring invasive surgery. Ayurvedic techniques have also been used alongside **chemotherapy** and surgery to assist patients in recovery and healing.

Description

Origins

Ayurvedic medicine originated in the early civilizations of India some 3,000-5,000 years ago. It is mentioned in the *Vedas*, the ancient religious and philosophical texts that are the oldest surviving literature in the world, which makes Ayurvedic medicine the oldest surviving healing system. According to the texts, Ayurveda was conceived by enlightened wise men as a system of living harmoniously and maintaining the body so that mental and spiritual awareness could be possible. Medical historians believe that Ayurvedic ideas were transported from ancient India to China and were instrumental in the development of Chinese medicine.

Today, Ayurvedic medicine is used by 80% of the population in India. Aided by the efforts of Deepak Chopra and the Maharishi, it has become an increasingly accepted alternative medical treatment in America during the last two decades. Chopra is an M.D. who has written several bestsellers based on Ayurvedic ideas. He also helped develop the Center for Mind/Body Medicine in La Jolla, California, a major Ayurvedic center that trains physicians in Ayurvedic principles, produces herbal remedies, and conducts research and documentation of its healing techniques.

Key ideas

To understand Ayurvedic treatment, it is necessary to have an idea how the Ayurvedic system views the body. The basic life force in the body is *prana*,

WWW.BOOKBAZ.IR

KEY TERMS

Dosha—One of three constitutional types, either vata, pitta, or kapha, found in Ayurvedic medicine.

Meditation—Technique of calming the mind.

Panchakarma—Intensive Ayurvedic cleansing and detoxification program.

Prakriti—An individual's unique dosha pattern.

Prana—Basic life energy found in the elements.

Yoga—System of body and breathing exercises.

which is also found in the elements and is similar to the Chinese notion of *chi*. As Swami Vishnudevananda, a yogi and expert, put it, "Prana is in the air, but is not the oxygen, nor any of its chemical constituents. It is in food, water, and in the sunlight, yet it is not vitamin, heat, or light-rays. Food, water, air, etc., are only the media through which the prana is carried."

In Ayurveda, there are five basic elements that contain prana: earth, water, fire, air, and ether. These elements interact and are further organized in the human body as three main categories or basic physiological principles in the body that govern all bodily functions known as the *doshas*. The three doshas are *vata, pitta, and kapha*. Each person has a unique blend of the three doshas, known as the person's *prakriti*, which is why Ayurvedic treatment is always individualized. In Ayurveda, disease is viewed as a state of imbalance in one or more of a person's doshas, and an Ayurvedic physician strives to adjust and balance them, using a variety of techniques.

The vata dosha is associated with air and ether, and in the body promotes movement and lightness. Vata people are generally thin and light physically, dry-skinned, and very energetic and mentally restless. When vata is out of balance, there are often nervous problems, hyperactivity, sleeplessness, lower back pains, and headaches.

Pitta is associated with fire and water. In the body, it is responsible for metabolism and digestion. Pitta characteristics are medium-built bodies, fair skin, strong digestion, and good mental concentration. Pitta imbalances show up as anger and aggression and stress-related conditions like **gastritis**, ulcers, liver problems, and hypertension.

The kapha dosha is associated with water and earth. People characterized as kapha are generally large or heavy with more oily complexions. They tend to be slow, calm, and peaceful. Kapha disorders manifest emotionally as greed and possessiveness, and physically as obesity, **fatigue**, **bronchitis**, and sinus problems.

Diagnosis

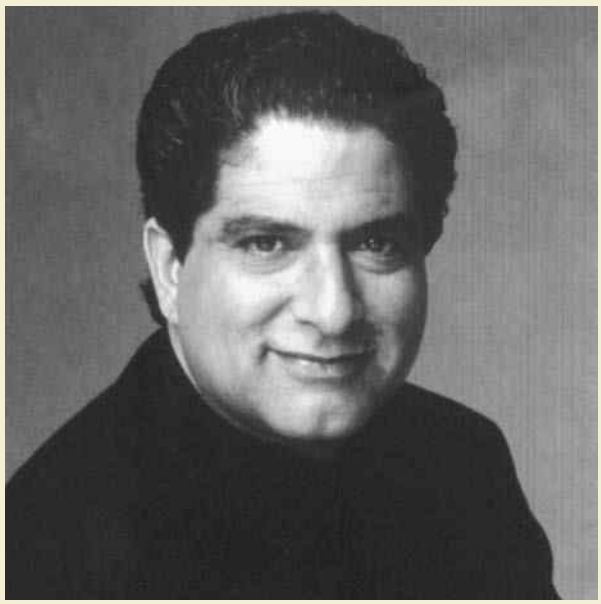
In Ayurvedic medicine, disease is always seen as an imbalance in the dosha system, so the diagnostic process strives to determine which doshas are underactive or overactive in a body. Diagnosis is often taken over a course of days in order for the Ayurvedic physician to most accurately determine what parts of the body are being affected. To diagnose problems, Ayurvedic physicians often use long questionnaires and interviews to determine a person's dosha patterns and physical and psychological histories. Ayurvedic physicians also intricately observe the pulse, tongue, face, lips, eyes, and fingernails for abnormalities or patterns that they believe can indicate deeper problems in the internal systems. Some Ayurvedic physicians also use laboratory tests to assist in diagnosis.

Treatment

Ayurvedic treatment seeks to re-establish balance and harmony in the body's systems. Usually the first method of treatment involves some sort of detoxification and cleansing of the body, in the belief that accumulated toxins must be removed before any other methods of treatment will be effective. Methods of detoxification include therapeutic **vomiting**, **laxatives**, medicated **enemas**, **fasting**, and cleansing of the sinuses. Many Ayurvedic clinics combine all of these cleansing methods into intensive sessions known as *panchakarma*. Panchakarma can take several days or even weeks and they are more than elimination therapies. They also include herbalized oil massage and herbalized **heat treatments**. After purification, Ayurvedic physicians use herbal and mineral remedies to balance the body as well. Ayurvedic medicine contains a vast knowledge of the use of herbs for specific health problems.

Ayurvedic medicine also emphasizes how people live their lives from day to day, believing that proper lifestyles and routines accentuate balance, rest, diet, and prevention. Ayurveda recommends yoga as a form of **exercise** to build strength and health, and also advises massage therapy and self-massage as ways of increasing circulation and reducing **stress**.

DEEPAK CHOPRA (1946–)



(AP Images.)

Deepak Chopra was born in India and studied medicine at the All India Institute of Medical Science. He left his home for the United States in 1970 and completed residencies in internal medicine and endocrinology. He went on to teaching posts at major medical institutions—Tufts University and Boston University schools of medicine—while establishing a very successful private practice. By the time he was 35, Chopra had become chief of staff at New England Memorial Hospital.

Disturbed by Western medicine's reliance on medication, he began a search for alternatives and discovered one in the teachings of the Maharishi Mahesh Yogi, an Indian spiritualist who had gained a cult following in the late sixties teaching Transcendental Meditation (TM). Chopra began practicing TM fervently and eventually met the Maharishi. In 1985 Chopra established the Ayurvedic Health Center for Stress Management and Behavioral Medicine in Lancaster, Massachusetts, where he began his practice of integrating the best aspects of Eastern and Western medicine.

In 1993, he published *Creating Affluence: Wealth Consciousness in the Field of All Possibilities*, and the enormously successful best seller, *Ageless Body, Timeless Mind*. In the latter he presents his most radical thesis: that aging is not the inevitable deterioration of organs and mind that we have been traditionally taught to think of it as. It is a process that can be influenced, slowed down, and even reversed with the correct kinds of therapies, almost all of which are self-administered or self-taught. He teaches that applying a regimen of nutritional balance, meditation, and emotional clarity characterized by such factors as learning to easily and quickly express anger, for instance, can lead to increased lifespans of up to 120 years.

Chopra, along with David Simon, M.D., opened the Chopra Center for Wellbeing in 1996, offering people experiences in physical healing, emotional freedom, and higher states of consciousness. Located in Carlsbad, California, the center offers a wide variety of programs, retreats, and teacher training programs that integrate the healing arts of the East with modern Western medicine. http://www.chopra.com/

Yogic breathing techniques and meditation are also part of a healthy Ayurvedic regimen, to reduce stress and improve mental energy.

Of all treatments, though, diet is one of the most basic and widely used therapy in the Ayurvedic system. An Ayurvedic diet can be a very well planned and individualized regimen. According to Ayurveda, there are six basic tastes: sweet, sour, salty, pungent, bitter, and astringent. Certain tastes and foods can either calm or aggravate a particular dosha. For instance, sweet, sour, and salty decrease vata problems and increase kapha. Sour, salty, and pungent can increase pitta. After an Ayurvedic physician determines a person's dosha profile, they will recommend a specific diet to correct imbalances and increase health. The Ayurvedic diet emphasizes primarily vegetarian foods of high quality and freshness, tailored to the season and time of day. Cooling foods are eaten in the summer and heating ones in the winter, always within a person's dosha requirements. In daily routine, the heaviest meal of the day should be lunch, and dinner should eaten well before bedtime, to allow for complete digestion. Also, eating meals in a calm manner with proper chewing and state of mind is important, as is combining foods properly and avoiding overeating.

Cost

Costs of Ayurvedic treatments can vary, with initial consultations running anywhere from $40 to over $100, with follow-up visits costing less. Herbal treatments may cost from $10 to $50 per

WWW.BOOKBAZ.IR

month, and are often available from health food or bulk herb stores. Some clinics offer panchakarma, the intensive Ayurvedic detoxification treatment, which can include overnight stays for up to several weeks. The prices for these programs can vary significantly, depending on the services and length of stay. Insurance reimbursement may depend on whether the primary physician is a licensed M.D.

Preparations

Ayurveda is a mind/body system of health that contains some ideas foreign to the Western scientific model. Those people considering Ayurveda should approach it with an open mind and willingness to experiment. Also, because Ayurveda is a whole-body system of healing and health, patience and discipline are helpful, as some conditions and diseases are believed to be brought on by years of bad health habits and require time and effort to correct. Finally, the Ayurvedic philosophy believes that each person has the ability to heal themselves, so those considering Ayurveda should be prepared to bring responsibility and participation into the treatment.

Precautions

An Ayurvedic practitioner should always be consulted.

Side effects

During Ayurvedic detoxification programs, some people report fatigue, muscle soreness, and general sickness. Also, as Ayurveda seeks to release mental stresses and psychological problems from the patient, some people can experience mental disturbances and depression during treatment, and psychological counseling may be part of a sound program.

Research and general acceptance

Because Ayurveda had been outside the Western scientific system for years, research in the United States is new. Another difficulty in documentation arises because Ayurvedic treatment is very individualized; two people with the same disease but different dosha patterns might be treated differently. Much more scientific research has been conducted over the past several decades in India. Much research in the United States is being supported by the Maharishi Ayur-Ved organization, which studies the Ayurvedic products it sells and its clinical practices.

Some Ayurvedic herbal mixtures have been proven to have high antioxidant properties, much stronger than **vitamins** A, C, and E, and some have also been shown in laboratory tests to reduce or eliminate tumors in mice and to inhibit cancer growth in human lung tumor cells. In a 1987 study at MIT, an Ayurvedic herbal remedy was shown to significantly reduce **colon cancer** in rats. Another study was performed in the Netherlands with Maharishi Ayur-Ved products. A group of patients with chronic illnesses, including asthma, chronic bronchitis, hypertension, **eczema**, **psoriasis**, constipation, **rheumatoid arthritis**, headaches, and non-insulin dependent **diabetes mellitus**, were given Ayurvedic treatment. Strong results were observed, with nearly 80% of the patients improving and some chronic conditions being completely cured.

Other studies have shown that Ayurvedic therapies can significantly lower **cholesterol** and blood pressure in stress-related problems. Diabetes, acne, and allergies have also been successfully treated with Ayurvedic remedies. Ayurvedic products have been shown to increase short-term memory and reduce headaches. Also, Ayurvedic remedies have been used successfully to support the healing process of patients undergoing chemotherapy, as these remedies have been demonstrated to increase immune system activity.

B

Babesiosis

Definition

Babesiosis is an infection of red blood cells caused by the single-celled parasite, *Babesia microti*, which is spread to humans by a tick bite.

Description

Babesiosis is a rare, tick-transmitted disease that is caused most often by the single-celled parasite *Babesia microti*. By 1995, fewer than 500 cases of babesiosis had been reported in the United States. The disease occurs primarily in New England and New York, especially on the coastal islands. However, cases have occurred in other parts of the United States. Because of tick activity, the risk for babesiosis is highest during June and July.

Ticks are small, blood-sucking arachnids. Although some ticks carry disease-causing organisms, most do not. *Babesia microti* is spread to humans through the bite of the tick *Ixodes scapularis* (also called *Ixodes dammini*). *Ixodes scapularis*, called the "blacklegged deer tick," usually feeds on deer and mice. A tick picks up the parasites by feeding on an infected mouse and then passes them on by biting a new host, possibly a human. To pass on the parasites, the tick must be attached to the skin for 36–48 hours. Once in the bloodstream, *Babesia microti* enters a red blood cell, reproduces by cell division, and destroys the cell, causing anemia. Humans infected with *Babesia microti* produce antibodies that can be helpful in diagnosing the infection.

Causes and symptoms

Babesia microti live and divide within red blood cells, destroying the cells and causing anemia. The majority of people who are infected have no visible symptoms. In those who become ill, symptoms appear one to six weeks following the tick bite. Because the ticks are small, many patients have no recollection of a tick bite. The symptoms are flu-like and include tiredness, loss of appetite, **fever**, drenching sweats, and muscle **pain**. Nausea, **vomiting**, **headache**, shaking chills, blood in the urine, and depression can occur.

Persons who are over 40 years old, have had their spleen removed (splenectomized), and/or have a serious disease (cancer, **AIDS**, etc.) are at a greater risk for severe babesiosis. In severe cases of babesiosis, up to 85% of the blood cells can be infected. This causes a serious, possibly fatal, blood deficiency.

Diagnosis

Babesiosis can be diagnosed by examining a blood sample microscopically and detecting the presence of *Babesia microti* within the blood cells. The blood can also be checked for the presence of antibodies to the parasite.

Treatment

In serious cases, babesiosis is treated with a combination of clindamycin (Cleocin) and quinine. Clindamycin is given by injection and quinine is given orally three to four times a day for four to seven days. To reduce the number of parasites in the blood, severely ill patients have been treated with blood transfusions.

Prognosis

Otherwise healthy patients will recover completely. Babesiosis may last several months without treatment and is a severe, potentially fatal disease in splenectomized patients.

Prevention

The only prevention for babesiosis is to minimize exposure to ticks by staying on trails when walking

KEY TERMS

Anemia—A below normal number of red blood cells in the bloodstream.

Parasite—An organism that lives upon or within another organism.

through the woods, avoiding tall grasses, wearing long sleeves and tucking pant legs into socks, wearing insect repellent, and checking for ticks after an outing. Remove a tick as soon as possible by grasping the tick with tweezers and gently pulling. Splenectomized people should avoid northeastern coastal regions during the tick season.

Bacillary angiomatosis

Definition

A life-threatening but curable infection that causes an eruption of purple lesions on or under the skin that resemble Kaposi's sarcoma. The infection, which occurs almost exclusively in patients with **AIDS**, can be a complication of **cat-scratch disease**.

Description

Bacillary angiomatosis is a re-emerging bacterial infection that is identical or closely related to one that commonly afflicted thousands of soldiers during World War I. In the early 2000s, the disease, caused by two versions of the same bacteria, is linked to homeless AIDS patients and to those afflicted with cat-scratch disease.

The infection is rarely seen today in patients who do not have HIV. According to the U.S. Centers for Disease Control and Prevention (CDC), an HIV patient diagnosed with bacillary angiomatosis is considered to have progressed to full-blown AIDS.

Causes and symptoms

Scientists have recently isolated two varieties of the Bartonella bacteria as the cause of bacillary angiomatosis: *Bartonella* (formerly *Rochalimaea-quintana*) and *B. henselae* (cause of cat-scratch disease).

B. quintana infection is known popularly as **trench fever** and is the infection associated with body lice that sickened European troops during World War I. Lice carry the bacteria, and can transmit the infection to humans. The incidence of trench **fever** was believed to have faded away with the end of World War I. It was not diagnosed in the United States until 1992, when 10 cases were reported among homeless Seattle men.

The related bacteria *B. henselae* was first identified several years ago as the cause of cat-scratch fever. It also can lead to bacillary angiomatosis in AIDS patients. Bacillary angiomatosis caused by this bacteria is transmitted to AIDS patients from cat fleas.

These two different types of bacteria both cause bacillary angiomatosis, a disease that is characterized by wildly proliferating blood vessels that form tumor-like masses in the skin and organs. The nodules that appear in bacillary angiomatosis are firm and do not turn white when pressed. The lesions can occur anywhere on the body, in numbers ranging from one to 100. They are rarely found on palms of the hands, soles of the feet, or in the mouth. As the number of lesions increase, the patient may develop a high fever, sweats, chills, poor appetite, **vomiting**, and weight loss. If untreated, the infection may be fatal.

In addition to the basic disease process, the two different types of bacteria cause some slightly different symptoms. Patients infected with *B. henselae* also experience blood-filled cysts within the liver and abnormal liver function, whereas *B. quintana* patients may have tumor growths in the bone.

Diagnosis

This life-threatening but curable infection is often misdiagnosed, because it may be mistaken for other conditions (such as Kaposi's sarcoma). A blood test developed in 1992 by the CDC detects antibodies to the bacteria. It can be confirmed by reviewing symptoms, history and negative tests for other diseases that cause swollen lymph glands. It is not necessary to biopsy a small sample of the lymph node unless there is a question of cancer of the lymph node or some other disease.

WWW.BOOKBAZ.IR

KEY TERMS

Cat-scratch disease—An infectious disease caused by bacteria transmitted by the common cat flea that causes a self-limiting, mild infection in healthy people.

Kaposi's sarcoma—A malignant condition that begins as soft brown or purple lesions on the skin and occurs most often in men with AIDS.

Treatment

Recent research indicates that **antibiotics** used to treat other HIV opportunistic infections can both prevent and treat bacillary angiomatosis. Treatment is usually given until the lesions disappear, which typically takes three or four weeks. A severely affected lymph node or blister may have to be drained, and a heating pad may help swollen, tender lymph glands. **Acetaminophen** (Tylenol) may relieve **pain**, aches, and fever over 101°F (38.3°C).

Prognosis

In most cases, prompt antibiotic treatment in patients with AIDS cured the infection caused by either variety of the bacteria, and patients may resume normal life. Early diagnosis is crucial to a cure.

Prevention

Studies suggest that antibiotics may prevent the disease. Patients also should be sure to treat cats for fleas.

Bacteremia

Definition

Bacteremia is an invasion of the bloodstream by bacteria.

Description

Bacteremia occurs when bacteria enter the bloodstream. This may occur through a wound or infection, or through a surgical procedure or injection. Bacteremia may cause no symptoms and resolve without treatment, or it may produce **fever** and other symptoms of infection. In some cases, bacteremia leads to **septic shock**, a potentially life-threatening condition.

Risk factors

Any opening through the skin and/or body orifices that allows for the entrance of bacteria into the body places an individual, particularly those with a compromised immune system, at increased risk for the development of bacteremia.

Conditions that increase the chances of developing bacteremia include:

- immune suppression, either due to HIV infection or drug therapy that suppresses the immune system
- antibiotic therapy, which changes the balance of bacterial types in the body
- prolonged or severe illness
- alcoholism or other drug abuse
- malnutrition
- diseases or drug therapy that cause ulcers in the intestines, such as chemotherapy for cancer

Causes and symptoms

Causes

Several types of bacteria live on the surface of the skin or colonize the moist linings of the urinary tract, lower digestive tract, and other internal surfaces. These bacteria are normally harmless as long as they are kept in check by the body's natural barriers and the immune system. People in good health with strong immune systems rarely develop bacteremia. However, when bacteria are introduced directly into the circulatory system, especially in a person who is ill or undergoing aggressive medical treatment, the immune system may not be able to cope with the invasion, and symptoms of bacteremia may develop. For this reason, bacteremia is most common in people who are already affected by or being treated for some other medical problem. In addition, medical treatment may bring a person in contact with new types of bacteria that are more invasive than those already residing in that person's body, further increasing the likelihood of bacterial infection.

KEY TERMS

Colostomy—Surgical creation of an artificial anus on the abdominal wall by cutting into the colon and bringing it up to the surface.

Gastrostomy—Surgical creation of an artificial opening into the stomach through the abdominal wall to allow tube feeding.

Jejunostomy—Surgical creation of an opening to the middle portion of the small intestine (jejunum), through the abdominal wall.

Septic shock—A life-threatening drop in blood pressure caused by bacterial infection.

Common immediate causes of bacteremia include:

- drainage of an abscess, including an abscessed tooth
- urinary tract infection, especially in the presence of a bladder catheter
- decubitus ulcers (pressure sores)
- intravenous procedures using unsterilized needles, including IV drug use
- prolonged IV needle placement
- use of ostomy tubes, including gastrostomy (surgically making a new opening into the stomach), jejunostomy (surgically making an opening from the abdominal wall into the jejunum), and colostomy (surgically creating an articifical opening into the colon)

The bacteria most likely to cause bacteremia include members of the *Staphylococcus*, *Streptococcus*, *Pseudomonas*, *Haemophilus,* and *Esherichia* (*E. coli*) genera.

Symptoms

Symptoms of bacteremia may include:

- fever over 101°F (38.3°C)
- chills
- malaise
- abdominal pain
- nausea
- vomiting
- diarrhea
- anxiety
- shortness of breath
- confusion

Not all of these symptoms may be present. In the elderly, confusion may be the only prominent symptom. Bacteremia may lead to septic **shock**, whose symptoms include decreased consciousness, rapid heart and breathing rates, and multiple organ failures.

Diagnosis

Tests

Bacteremia is diagnosed by culturing the blood for bacteria. Samples may need to be tested several times over several hours. Blood analysis may also reveal an elevated number of white blood cells.

Treatment

Bacteremia may cause no symptoms, but may be discovered through a blood test for another condition. In this situation, it may not need to be treated, except in patients especially at risk for infection, such as those with heart valve defects or whose immune systems are suppressed.

Drugs

Prompt antibiotic therapy usually succeeds in clearing bacteria from the bloodstream. Recurrence may indicate an undiscovered site of infection. Untreated bacteria in the blood may spread, causing infection of the heart (**endocarditis** or **pericarditis**) or infection of the covering of the central nervous system (**meningitis**).

Blood pressure is monitored closely; a decline in blood pressure may indicate the onset of septic shock.

Prognosis

If detected and treated promptly, most individuals recover from bacteremia. However, in individuals whose immune systems are compromised, it is critical that the condition be treated promptly and aggressively so that it does not progress to **sepsis** or septic shock, which can lead to death even if treatment is initiated.

Prevention

Bacteremia can be prevented by preventing the infections that often precede it. Good personal hygiene such as effective hand-washing, especially during viral illness, may reduce the risk of developing bacterial infection. Treating bacterial infections quickly and thoroughly can minimize the risk of spreading infection. During medical procedures, the burden falls on medical professionals to minimize the number and duration of invasive procedures, to reduce patients'

WWW.BOOKBAZ.IR

exposure to sources of bacteria when being treated, and to use scrupulous technique.

Bacterial vaginosis

Definition

Bacterial vaginosis (BV) is a type of vaginal infection in which the normal balance of bacteria in the vagina is disrupted, allowing the overgrowth of harmful anaerobic bacteria at the expense of protective bacteria.

Description

BV is the most common and the most serious type of vaginal infection in women of childbearing age. As many as 10–26% of pregnant women in the United States have BV; BV has been found in 12–25% of women in routine clinic populations, and in 32 to 64 percent of women in clinics for sexually transmitted diseases (STDs). BV is different than vaginal yeast infections and requires different methods of treatment.

In most cases, BV does not have lasting effects on women. However, there can be risks associated with BV:

Causes and symptoms

Bacteria that dominate the vaginal flora in a BV infection include *Gardnerella vaginalis* or *Mobiluncus*, although other bacteria, such as *Escherichia coli* from the rectum have also been shown to cause the disease. The overgrowth of these harmful bacteria are at the expense of the protective bacteria lactobacilli, which secrete a natural disinfectant, hydrogen peroxide, that maintains the healthy, normal balance of vaginal microorganisms. The factors that upset the normal balance of bacteria in the vagina are not well understood; however, the following activities or behaviors that have been associated with BV include:

KEY TERMS

Anaerobic bacteria—Bacteria that do not require oxgyen, found in low concentrations in the vagina.

Vaginal discharge—Discharge of secretions from the cervical glands of the vagina; normally clear or white.

- having a new sex partner or multiple sex partners
- stress
- douching
- using an intrauterine device (IUD) for contraception

BV is not transmitted through toilet seats, bedding, swimming pools, or touching of objects. Women who have not had sexual intercourse rarely have BV. BV is not considered an STD, although it does appear to act like an STD in women who have sex with women.

The main symptom of BV is a thin, watery or foamy, white (milky) or gray vaginal discharge with an unpleasant, foul, fish-like or musty odor. The odor is sometimes stronger after a woman has sex, when the semen mixes with the vaginal secretions. Burning or **pain** during urination can also be present with BV. **Itching** on the outside of the vagina and redness can also occur, but are seen less frequently. However, many women with BV do not exhibit any symptoms.

Diagnosis

BV is diagnosed through an examination of the vagina by a healthcare provider. A woman who suspects that she may have BV should not douche or use a feminine hygiene spray before the appointment with the healthcare provider. Laboratory tests are conducted on a sample of the vaginal fluid to see if the bacteria present are those associated with BV. The healthcare provider may also check to see if there is decreased vaginal acidity. Potassium hydroxide, when added to a vaginal discharge sample, enhances vaginal odors and allows the health care provider to determine if the odor is fishy or foul.

Treatment

In a few cases, BV might clear up without treatment. However, all women with symptoms of BV should be treated to relieve symptoms and to avoid the development of complications such as **pelvic inflammatory disease** (PID). In most cases, male partners are not treated, but female sexual partners should be examined to see if they have BV and require treatment.

BV is treated with prescription **antibiotics** such as metronidazole or clindamycin creams or oral metronidazole (both are antibiotics that can also be used by pregnant women, although at different doses). Metronidazole kills anaerobic bacteria but does not harm the protective lactobacilli. Drinking alcohol should be avoided when taking metronidazole, for this medicine can cause severe **nausea and vomiting** when combined with alcohol.

For postmenopausal women, in addition to the use of antibiotics, the healthcare provider may also prescribe estrogen suppositories or topical cream to thicken and lubricate vaginal tissues. Sexual activity should be avoided during treatment; a condom should be used if the woman does have sexual intercourse. The woman should be tested after treatment to ensure that the infection has been cured.

Alternatives

Supplement therapies are available in addition to the use of prescription medicines to ease recovery.

Herbal therapies

Fresh garlic (*Allium sativum*) has antibacterial properties and can be added to a woman's diet. A fresh, peeled garlic wrapped in gauze can also be inserted into the vagina to help treat BV. The insert should be changed twice daily.

To soothe itching or irritation of the vaginal tissues, a woman can bathe the tissues in an infusion of fresh chickweed (*Stellaria media*). The infusion is made by pouring one cup of boiling water on one to two teaspoons of the herb, steeping for five minutes, and allowing the mixture to cool before use.

Prognosis

- Pregnant women with BV often have babies of low birth weight (less than 5.5 pounds) or who are premature.
- Bacteria that cause BV may also cause pelvic inflammatory disease (PID), an infection of the uterus and fallopian tubes. The risk of a woman with BV developing PID is higher after the woman undergoes surgical procedures such as a hysterectomy or an abortion. PID can result in infertility and can also increase the risk of an ectopic pregnancy.
- BV may increase the risk of a woman becoming infected with HIV, the virus that causes AIDS.
- A woman with BV and HIV is more likely to pass HIV to her sexual partner.
- BV increases the chance that a woman will contract other STDs, such as chlamydia and gonorrhea.

BV can be successfully treated with antibiotics.

Prevention

Since the development of BV often appears to be associated with sexual activities, recommended ways to avoid BV include:

- practicing abstinence
- delaying having sex for the first time, as younger people who have sex are more likely to contract BV and STDs
- limiting the number of sexual partners
- having a sexual relationship with only one partner who does not have an STD
- practicing safer sex, which means using a condom every time when having sex

Other ways to prevent BV include:

- discontinuing the use of tampons for six months
- practicing good hygiene by wiping from front to back (away from the vagina) after bowel movements to avoid spreading bacteria from the rectum to the vagina
- wearing cotton panties and panty hose with a cotton crotch and avoiding tight or latex clothing to keep the vagina cool and dry
- avoiding the use of perfumed soaps and feminine sprays
- lowering stress levels
- avoiding douching, as douching removes some of the normal bacteria in the vagina that protects women from infection
- finishing the course of antibiotic treatment, even if the symptoms are relieved, to prevent reoccurrence of the disease
- routinely being tested for BV during regular gynecological examinations

Some physicians recommend that all women who have a **hysterectomy** or an abortion be treated for BV, to reduce the risk of developing PID.

Bad breath

Definition

Bad breath, sometimes called halitosis, is an unpleasant odor of the breath.

Description

Bad breath is likely to be experienced by most adults at least occasionally. Bad breath, either real or imagined, can have a significant impact on a person's social and professional life.

Causes and symptoms

Bad breath can be caused by a number of problems. Oral diseases, fermentation of food particles in the mouth, sinus infections, and unclean dentures can all contribute to mouth odor. Many non-oral diseases, such as lung infections, kidney failure, or severe **liver disease**, can also cause bad breath, though rarely. Many people think that bad breath can originate in the stomach or intestines; this is extremely rare. The esophagus is usually collapsed and closed, and, although a belch may carry odor up from the stomach, the chance of bad breath being caused from air continually escaping from the stomach is remote. Cigarette smoke can cause bad breath, not only in the cigarette smoker, but also in one who is constantly exposed to secondhand smoke.

Diagnosis

The easiest way to determine if one has bad breath is to ask someone who is trustworthy and discrete. This is usually not too difficult. Another, more private, method of determining if one has bad breath is to lick one's wrist, wait until it dries, then smell the area.

KEY TERMS

Halitosis—The medical term for bad breath.

Scraping the rear area of the tongue with a plastic spoon, then smelling the spoon, is another method one can use to assess bad breath.

Treatment

The most effective treatment of bad breath is to treat the cause. Poor **oral hygiene** can be improved by regular brushing and flossing, as well as regular dental checkups. Gentle brushing of the tongue should be part of daily oral hygiene. In addition to good oral hygiene, the judicious use of mouthwash is helpful. Mouth dryness, experienced at night or during **fasting**, or due to certain medications and medical conditions, can contribute to bad breath. Dryness can be avoided by drinking adequate amounts of water. Chewing gum may be beneficial.

As mentioned, some medications, such as some high blood pressure medications, can cause **dry mouth**. If this problem is significant, a medication change, under the supervision of one's healthcare provider, may improve the dry-mouth condition. Oral or sinus infections, once diagnosed, can be treated medically, usually with **antibiotics**. Lung infections and kidney or liver problems will, of course, need medical treatment.

Alternatives

Depending on the cause, a multitude of alternative therapeutic remedies can be used. For example, **sinusitis** can be treated with steam inhalation of essential oils and/or herbs.

Prognosis

Most bad breath can be treated successfully with good oral hygiene and/or medical care. Occasionally, for patients who feel that these therapies are unsuccessful, some delusional or obsessive behavior pattern might pertain, and mental health counseling may be appropriate.

Balance and coordination tests

Definition

Balance is the ability to maintain a position. Coordination is the capacity to move through a complex set of movements. Balance and coordination depend on the interaction of multiple body organs and systems including the eyes, ears, brain and nervous system, cardiovascular system, and muscles. Tests or examination of any or all of these organs or systems may be necessary to determine the causes of loss of balance, **dizziness**, or the inability to coordinate movement or activities.

Purpose

Tests of balance and coordination, and the examination of the organs and systems that influence balance and coordination, can help to identify causes of dizziness, **fainting**, falling, or incoordination.

A patient sits on a ball, working on his balance. He wears a belt so that the physical therapist can catch him if he loses balance. *(Custom Medical Stock Photo, Inc.)*

Precautions

Tests for balance and coordination should be conducted in a safe and controlled area where patients will not experience injury if they become dizzy or fall.

Description

Assessment of balance and coordination can include discussion of the patient's medical history and a complete **physical examination** including evaluation of the heart, head, eyes, and ears. A slow pulse or heart rate, or very low blood pressure may indicate a circulatory system problem, which can cause dizziness or fainting. During the examination, the patient may be asked to rotate the head from side to side while sitting up or while lying down with the head and neck extended over the edge of the examination table. If these tests produce dizziness or a rapid twitching of the eyeballs (**nystagmus**), the patient may have a disorder of the inner ear, which is responsible for maintaining balance.

An examination of the eyes and ears may also give clues to episodes of dizziness or incoordination. The patient may be asked to focus on a light or on a distant point or object, and to look up, down, left, and right moving only the eyes while the eyes are examined. Problems with vision may, in themselves, contribute to balance and coordination disturbances, or may indicate more serious problems of the nervous system or brain function. **Hearing loss**, fluid in the inner ear, or ear infection might indicate the cause of balance and coordination problems.

Various physical tests may also be used. A patient may be asked to walk a straight line, stand on one foot, or touch a finger to the nose to help assess balance. The patient may be asked to squeeze or push against the doctor's hands, to squat down, to bend over, stand on tiptoes or stand on their heels. Important aspects of these tests include holding positions for a certain number of seconds, successfully repeating movements a certain number of times, and repeating the test accurately with eyes closed. The patient's reflexes may also be tested. For example, the doctor may tap on the knees, ankles, and elbows with a small rubber mallet to test nervous system functioning. These tests may reveal muscle weakness or nervous system problems that could contribute to incoordination.

Preparation

No special preparation is required prior to administration of balance and coordination tests. The patient may be asked to disrobe and put on an examination gown to make it easier for the doctor to observe muscles and reflex responses.

WWW.BOOKBAZ.IR

KEY TERMS

Meniere's disease—An abnormality of the inner ear that causes dizziness, ringing in the ears, and hearing loss.

Aftercare

No special aftercare is generally required, however, some of the tests may cause episodes of dizziness or incoordination. Patients may need to use caution in returning to normal activities if they are experiencing any symptoms of dizziness, lightheadedness, or weakness.

Risks

These simple tests of balance and coordination are generally harmless.

Results

Under normal conditions, these tests will not cause dizziness, loss of balance, or incoordination.

Abnormal results

The presence of dizziness, lightheadedness, loss of coordination, unusual eye movements, muscle weakness, or impaired reflexes are abnormal results and may indicate the problem causing the loss of balance or incoordination. In some cases, additional testing may be needed to diagnose the cause of balance or coordination problems.

Altha Roberts Edgren

Balanitis

Definition

Balanitis is an inflammation of the head and foreskin of the penis.

Description

Balanitis generally affects uncircumcised males. These are men who have a foreskin, which is the "hood" of soft skin that partially covers the head of the penis. In balanitis, the head and foreskin become red and inflamed. (In circumcised men, who lack a foreskin, these symptoms only affect the tip of the penis.) The condition often occurs due to the fungus *Candida albicans*, the same organism that causes vaginal yeast infections in women. Balanitis (which is also referred to as balanoposthitis) can be caused by a variety of other fungal or bacterial infections, or may occur due to a sensitivity reaction to common chemical agents.

Uncircumcised men are more at risk for balanitis due to the presence of the foreskin. The snug fit of the foreskin around the top of the penis tends to create a damp, warm environment that encourages the growth of microorganisms. Most of the organisms associated with balanitis are already present on the penis, but in very small numbers. However, if the area between the head and foreskin is not cleansed thoroughly on a regular basis, these organisms can multiply and lead to infection.Diabetes can increase the risk of developing the condition.

Causes and symptoms

Balanitis is usually a result of poor hygiene—for example, neglecting to bathe for several days. A failure to properly wash (or rinse) the area between the head and foreskin can lead to the development of fungal or bacterial infections that cause the condition. In other cases, balanitis may occur due to an allergic reaction: some men may be sensitive to chemicals found in harsh soaps, laundry detergents, or contraceptive creams. Men who contract a sexually transmitted disease (STD) such as trichimoniasis may also develop symptoms.

The symptoms of balanitis are limited to the foreskin and head of the penis (in circumcised men, only the head is affected). These include redness, inflammation, **pain**, discharge, sore or itchy skin, and difficulty retracting the foreskin.

Diagnosis

Balanitis is usually diagnosed based on a brief **physical examination**. This may be conducted by your regular healthcare provider or by a urologist, the type of doctor who specializes in such disorders. The doctor may take a sample of the discharge (if any) to determine the nature of the possible infection. A urine test may be recommended to evaluate glucose

KEY TERMS

Acidophilus—A bacteria believed to combat yeast infections.

Circumcision—The surgical removal of the foreskin.

Urethral stricture—A narrowing of the urethra (urine tube).

(sugar) levels in the urine. Balanitis treatment is typically covered by medical insurance.

Treatment

The treatment of balanitis depends on the specific cause, which can vary from case to case. **Antibiotics** are used to treat bacterial infections, while topical antifungals such as clotrimazole can combat balanitis caused by *Candida*. If an allergic reaction is causing symptoms, the goal is to identify the chemical agent responsible. Ointments or creams may be used to ease skin irritation.

No matter what the cause, it is important to thoroughly clean the penis on a daily basis in order to alleviate symptoms. If the condition keeps occurring, or if the inflammation is interfering with urination, **circumcision** may be advised.

Alternatives

According to practitioners of alternative medicine, certain herbs may be effective in controlling or preventing yeast infections—a common cause of balanitis. These remedies include garlic, calendula, and goldenseal. Eating yogurt that contains acidophilus may also help to clear up a *Candida* infection.

Prognosis

Most cases go away quickly once the cause is identified and treated. However, regular bouts of balanitis can result in urethral stricture.

Prevention

Proper hygiene is the best way to avoid balanitis. Circumcision is sometimes performed to prevent repeated cases.

Balantidiasis

Definition

Balantidiasis is an **infectious disease** produced by a single-celled microorganism (protozoan) called *Balantidium coli* that infects the digestive tract. It is primarily a disease of the tropics, although it is also found in cooler, temperate climates. Most persons with balantidiasis do not exhibit any noticeable symptoms (asymptomatic), but a few individuals will develop **diarrhea** with blood and mucus and an inflamed colon (**colitis**).

Description

Balantidiasis is caused by *Balantidium coli*, a parasitic protozoan that infects the large intestine. *B. coli* is the largest and only protozoan, having cilia or hair-like structures, that is capable of causing disease in humans. Balantidiasis occurs most commonly in areas with poor sanitation and in settings where humans live in close contact with pigs, sheep, or goats.

Causes and symptoms

Balantidiasis is transmitted primarily by eating food or drinking water that has been contaminated by human or animal feces containing *B. coli* cysts. During its life cycle, this organism exists in two very different forms: the infective cyst or capsuled form, which cannot move but can survive outside the human body because of its thick, protective covering; and the disease-producing form, the trophozoite, which although capable of moving, cannot survive once excreted in the feces and, therefore, cannot infect others. In the digestive tract, the cysts are transported to the intestine where the walls of the cysts are broken open by digestive secretions, releasing the mobile trophozoites. Once released within the intestine, the trophozoites multiply by feeding on intestinal bacteria or by invading the lining of the large intestine. Within the lining of the large intestine, the trophozoites secrete a substance that destroys intestinal tissue and creates sores (**ulcers**) or abscesses. Trophozoites eventually form new cysts that are carried through the

WWW.BOOKBAZ.IR

KEY TERMS

Asymptomatic—Describes persons who carry a disease and are usually capable of transmitting the disease but who do not exhibit symptoms of the disease are said to be asymptomatic.

Biopsy—The removal of a tissue sample for diagnostic purposes.

Ciliated—Covered with short, hair-like protrusions, like *B. coli* and certain other protozoa. The cilia or hairs help the organism to move.

Colitis—An inflammation of the large intestine that occurs in some cases of balantidiasis. It is marked by cramping pain and the passing of bloody mucus.

Protozoan—A single-celled, usually microscopic organism, such as *B. coli*, that is eukaryotic and, therefore, different from bacteria (prokaryotic).

Sigmoidoscopy—A procedure in which a thin, flexible, lighted instrument, called a sigmoidoscope, is used to visually examine the lower part of the large intestine.

digestive tract and excreted in the feces. Under favorable temperature and humidity conditions, the cysts can survive in soil or water for weeks to months, ready to begin the cycle again.

Most individuals with balantidiasis have no noticeable symptoms. Even though these individuals may not feel ill, they are still capable of infecting others by person-to-person contact or by contaminating food or water with cysts that others may ingest, for example, by preparing food with unwashed hands.

The most common symptoms of balantidiasis are chronic diarrhea or severe colitis with abdominal cramps, **pain**, and bloody stools. Complications may include intestinal perforation in which the intestinal wall becomes torn, but the organisms do not spread to other parts of the body in the blood stream.

Diagnosis

Diagnosis of balantidiasis, as with other similar diseases, can be complicated, partly because symptoms may or may not be present. A diagnosis of balantidiasis may be considered when a patient has diarrhea combined with a possible history of recent exposure to **amebiasis** through travel, contact with infected persons, or anal intercourse.

Specifically, a diagnosis of balantidiasis is made by finding *B. coli* cysts or trophozoites in the patient's stools or by finding trophozoites in tissue samples (biopsy) taken from the large bowel. A diagnostic blood test has not yet been developed.

Stool examination

This test involves microscopically examining a stool sample for the presence of cysts and/or trophozoites of *B. coli*.

Sigmoidoscopy

To take a tissue sample from the large intestine, a procedure called a **sigmoidoscopy** is performed. During a sigmoidoscopy, a thin, flexible instrument is used to visually examine the intestinal lining and obtain small tissue specimens.

Treatment

Patients with balantidiasis are treated with prescription medication, typically consisting of a ten-day course of either tetracycline or metronidazole. Alternative drugs that have proven effective in treating balantidiasis include iodoquinol or paromomycin.

Prognosis

Although somewhat dependent on the patient's overall health, in general, the prognosis for most patients with balantidiasis is good. Severely infected patients occasionally die as a result of a tear in the intestinal wall (intestinal perforation) and consequent loss of blood.

Prevention

There are no immunization procedures or medications that can be taken prior to potential exposure to prevent balantidiasis. Moreover, people who have had the disease can become reinfected. Prevention requires effective personal and community hygiene. Specific safeguards include the following:

- Purification of drinking water. Water can be purified by filtering, boiling, or treatment with iodine.
- Proper food handling. Measures include protecting food from contamination by flies, cooking food properly, washing one's hands after using the bathroom and before cooking or eating, and avoiding foods that cannot be cooked or peeled when traveling in countries with high rates of balantidiasis.
- Careful disposal of human feces.
- Monitoring the contacts of balantidiasis patients. The stools of family members and sexual partners of infected persons should be tested for the presence of cysts or trophozoites.

Balloon valvuloplasty

Definition

Balloon valvuloplasty, also called percutaneous balloon valvuloplasty, is a surgical procedure used to open a narrowed heart valve. The procedure is sometimes described as balloon enlargement of a narrowed heart valve.

Purpose

Balloon valvuloplasty is performed on children and adults who have a narrowed heart valve, a condition called stenosis. The goal of the procedure is to improve valve function and blood flow by enlarging the valve opening. It is sometimes used to avoid or delay open heart surgery and valve replacement.

There are four valves in the heart: aortic valve, pulmonary valve, mitral valve, and tricuspid valve. Each is located at the exit of one of the heart's four chambers. These valves open and close to regulate the blood flow from one chamber to the next and are vital to the efficient functioning of the heart and circulatory system. Balloon valvuloplasty is used primarily to treat pulmonary, mitral, and aortic valves when narrowing is present and medical treatment has not corrected or relieved the related problems. With mitral stenosis, for example, medical solutions are typically tried first, such as diuretic therapy (reducing excess fluid), anticoagulant therapy (thinning the blood and preventing **blood clots**), or blood pressure medications. Valvuloplasty is recommended for those patients whose symptoms continue to progress even after taking such medications for a period of time.

Valvular stenosis can be a congenital defect (develops in the fetus and is present at birth) or it can be acquired; that is, it stems from other conditions. **Mitral valve stenosis** in adults, for example, is rarely congenital and is usually acquired, either a result of having **rheumatic fever** as a child or developing **calcium** obstruction in the valve later in life. Pulmonary stenosis is almost entirely congenital. Aortic stenosis usually does not produce symptoms until the valve is 75% blocked; this occurs over time and is consequently found in people between the ages of 40 and 70. Tricuspid stenosis is usually the result of rheumatic **fever**; it occurs less frequently than other valve defects.

Childhood symptoms of valve narrowing may include heart dysfunction, **heart failure**, blood pressure abnormalities, or a murmur. Adult symptoms will likely mimic **heart disease** and may include blood pressure abnormalities, **shortness of breath**, chest **pain** (**angina**), irregular heart beat (arrhythmia), or **fainting** spells (syncope). Electrocardiogram (EKG), x ray, and **angiography** (a special x-ray examination using dye in the vascular system) may be performed to identify valvular heart problems. Depending on the severity of symptoms, **cardiac catheterization** may also be performed to examine heart valve function prior to recommending a surgical procedure. Valvular **angioplasty** is performed in children and adults to relieve stenosis. While it offers relief, it does not always cure the problem—particularly in adults—and often valvotomy (cutting the valve leaflets to correct the opening) or valve replacement is necessary at a later date.

Demographics

Congenital heart-valve disease occurs in one of every 1,000 newborns and is thought to be caused by inherited factors. In 2%–4% of valve problems, health or environmental factors affecting the mother during **pregnancy** are believed to contribute to the defect. **Pulmonary valve stenosis** represents about 10% of all congenital heart problems. About 5% of all cardiac defects is stenosis of the aortic valve. Valve abnormalities are diagnosed in children and adults of both sexes; 80% of adult patients with stenosis are male, while most adults with mitral stenosis are women who had rheumatic fever as a child. Tricuspid stenosis is rarely found in North America or Europe.

Description

Balloon valvuloplasty is performed in a hospital cardiac catheterization laboratory, a special room much like an operating room. The procedure is performed by a cardiologist or vascular surgeon.

In balloon valvuloplasty, a thin tube (catheter) with a small deflated balloon at its tip (balloon-tipped catheter) is inserted through an incision in the skin in the groin area into a vein, and then is threaded up to the opening of the narrowed heart valve. The balloon is inflated to stretch the valve open and relieve the valve obstruction.

WWW.BOOKBAZ.IR

KEY TERMS

Cardiac catheterization—A minimally invasive technique that runs a catheter through veins into the heart to evaluate heart function. Fluoroscopy is used to observe the catheterization.

Dilate—To expand or open a valve or blood vessel.

Electrocardiography (EKG)—A method to measure variations in the actions of the heart. An EKG machine produces wave-like patterns either on paper or on a monitor that can be used to diagnose irregularities in rhythm.

Stenosis—The narrowing of any valve, especially one of the heart valves or the opening into the pulmonary artery from the right ventricle.

Valve—Flaps (leaflets) of tissue in passageways such as exist between the heart's upper and lower chambers.

The procedure, which takes up to four hours, is performed in a cardiac catheterization laboratory that has a special x-ray machine and an x-ray monitor that looks like a regular TV screen. The patient will be placed on an x-ray table and covered with a sterile sheet. An area on the inside of the upper leg will be washed and treated with an antibacterial solution to prepare for the insertion of a catheter. The patient is given local **anesthesia** to numb the insertion site and will usually remain awake, able to watch the procedure on the monitor. After the insertion site is prepared and anesthetized, the cardiologist inserts a catheter into the appropriate blood vessel, and then passes the smaller balloon-tipped catheter through the first catheter. Guided by the x-ray monitor that allows visualization of the catheter in the blood vessel, the physician slowly threads the catheter up into the coronary artery to the heart. The deflated balloon is carefully positioned in the opening of the valve that is being treated, and then is inflated repeatedly, which applies pressure to dilate the valve. The inflated balloon widens the valve opening by splitting the valve leaflets apart. Once the valve is widened, the balloon-tipped catheter is removed. The other catheter remains in place for 6–12 hours because, in some cases, the procedure must be repeated. A double-balloon valvuloplasty procedure is often performed on certain high-risk patients because it is considered more effective in restoring blood flow.

Preparation

For at least six hours before balloon valvuloplasty, the patient will have to avoid eating or drinking anything. An intravenous line is inserted so that medications (anticoagulants to prevent clot formation and radioactive dye for x rays) can be administered. The patient's groin area is shaved and cleaned with an antiseptic. About an hour before the procedure, the patient is given an oral sedative such as diazepam (Valium) to ensure that he or she will relax sufficiently for the procedure.

Aftercare

After balloon valvuloplasty, the patient will spend several hours in the recovery room to be monitored for vital signs (such as heart rate and breathing) and heart sounds. During this time, electrical leads attached to an EKG machine will be placed on the patient's chest and limbs, and a monitor will display the electrical impulses of the heart continuously, alerting nurses quickly if any abnormality occurs. For at least 30 minutes after removal of the catheter, direct pressure is applied to the site of insertion; after this, a pressure dressing will be applied. The skin condition is monitored. The insertion site will be observed for bleeding until the catheter is removed. The leg in which the catheter was inserted is temporarily prevented from moving. Intravenous fluids will be given to help eliminate the x-ray dye; intravenous anticoagulants or other medications may be administered to improve blood flow and to keep coronary arteries open. Pain medication is administered as needed. Some patients will continue to take anticoagulant medications for months or years after the surgery and will have regular blood tests to monitor the effectiveness of the medication.

Following **discharge from the hospital**, the patient can usually resume normal activities. After balloon valvuloplasty, lifelong follow-up is necessary because valves sometimes degenerate or narrowing recurs, a condition called restenosis, which will likely require repeat valvuloplasty, valvotomy, or valve replacement.

Risks

Balloon valvuloplasty can have serious complications. For example, the valve can become misshapen so that it does not close completely, which makes the condition worse. **Embolism**, where either clots or pieces of valve tissue break off and travel to the brain or the lungs causing blockage, is another possible risk. If the procedure causes severe damage to the valve leaflets, immediate valve replacement is required. Less frequent complications are bleeding and hematoma (a local collection of clotted blood)

at the puncture site, abnormal heart rhythms, reduced blood flow, **heart attack**, heart puncture, infection, and circulatory problems. Because restenosis is frequent in adult patients with valvular disease, particularly when underlying heart disease or other conditions are present, the procedure is recommended only as an emergency rescue for high-risk patients who are not candidates for valve replacement.

Results

Balloon valvuloplasty is considered a safe, effective treatment in children with congenital stenosis, improving heart function and blood flow. In adults, balloon valvuloplasty may give temporary relief and improve heart function and blood flow, but underlying **coronary artery disease** or other disease conditions may encourage restenosis, making valve replacement eventually necessary. The most successful valvuloplasty results are achieved in treating narrowed pulmonary valves, although the treatment of mitral valve stenosis is also generally good. The aortic valve procedure is more difficult to perform and is generally less successful.

Bandages and dressings

Definition

Bandages and dressings are both used in wound management. A bandage is a piece of cloth or other material used to bind or wrap a diseased or injured part of the body. Usually shaped as a strip or pad, bandages are either placed directly against the wound or used to bind a dressing to the wound. A dressing can consist of a wide range of materials—sometimes containing medication—placed directly against the wound.

Purpose

The purposes served by dressings include protecting **wounds**; promoting healing; and providing, retaining, or removing moisture. Bandages can be used to hold dressings in place, to relieve **pain**, and generally to make the patient comfortable. Elastic bandages are useful to provide ongoing pressure on wounds such as **varicose veins**, fractured ribs, and swollen joints.

Description

In recent years, there have been tremendous advances in the design and composition of bandages and dressings. The field is becoming increasingly complex, and there are numerous reports of healthcare workers applying inappropriate products. Wound-care materials come in a wide variety of product classes, including the following:

- Alginate dressings. These are derived from brown seaweed and contain calcium alginate, which turns into a sodium alginate gel when it comes in contact with wound fluid. They are available as pads or ropes.
- Biosynthetic dressings. These are composites of biological (often animal-derived) and synthetic materials such as polymers.

WWW.BOOKBAZ.IR

- Collagen dressings. These are made from collagen, a protein obtained from cowhide, cattle tendons, or birds. They are available as particles or gels.
- Composite dressings. These are similar to plastic adhesive strips and include an adhesive border, a nonadhesive or semi-adhesive surface that is applied to the wound, an absorbent layer, and a bacterial barrier.
- Contact layers. A low-adherent layer of perforated or woven polymer material designed to stop a secondary absorbent dressing from sticking to the surface of a wound.
- Gauze. This woven fabric of absorbent cotton is available in a number of formats and materials, including cotton or synthetic; non-impregnated; and impregnated with water, saline, or other substances. Gauze is sold as surgical swabs, sheets, rolls, pads, sponges, and ribbon.
- Growth factors. These short-chain proteins affect specific target cells. They exist naturally in humans and can be transplanted from one part of the body to another or manufactured outside the body.
- Hydrocolloid dressings. Used for leg ulcers, minor burns, pressure sores and traumatic injuries, these self-adhesive dressings form a gel as they absorb fluid from the wound. They consist of materials such as sodium carboxymethylcellulose (an absorbent), pectin, and gelatin that are attached to a foam sheet or a thin polyurethane film.
- Hydrofibers. Similar in appearance to cotton, carboxymethylcellulose fibers turn into a gel when they come into contact with wound fluid. They are available as ribbons or pads and are highly absorbent.
- Hydrogels. These are sold as sheets and in gel form, and are primarily used to supply moisture to wounds. Depending on the state of the tissue, they can either absorb fluid or moisten the wound. An electrically conductive aloe vera gel is available to provide electrotherapy to wounds.
- Hydropolymers. These foamed-gel products consist of multiple layers. The surface layer is designed to expand to fill the contours of a wound and draw away fluids.
- Leg compression/wrapping products. These are designed to apply external pressure to improve blood flow and resolve chronic edema in the feet and legs. They are available in a broad range of formats, including stockings, compression bandages, or pneumatic pump.
- Polyurethane foam dressings. These are sheets of foamed polymer solutions with small open chambers that draw fluids away from the wound. Some of these foam products offer adhesive surfaces. They are available as sheets and rolls, as well as in various other formats suitable for packing wounds.
- Skin substitutes. Also known as allografts or skin equivalents, these are obtained from human cells cultured and expanded in vitro from neonatal foreskins.
- Superabsorbents. These are particles, hydropolymers, or foams that act like the material inside diapers, with a high capacity for rapid absorption.
- Transparent films. These consist of a thin, clear polyurethane sheet that, on one side, has a special adhesive that does not stick to moist surfaces like those found on a wound. They prevent bacteria and fluids from entering the wound through the dressing, but allow limited circulation of oxygen.
- Wound fillers. These can be bought as powders or pastes, or in strands or beads. They are used to fill wounds and also absorb wound fluid.
- Wound pouches. Equipped with a special collection system for wounds that have a high flow of secretion, they are designed to contain odors and to be easily drained.
- Other assorted wound-care products. These include adhesive bandages, surgical tapes, adhesive skin closures, surgical swabs, paste bandages, specialty absorptive dressings, support bandages, retention bandages, elasticized tubular bandages, lightweight elasticized tubular bandages, foam-padded elasticized tubular bandages, and plain stockinettes.

Just as there is a large selection of bandage and dressing products to choose from, there is also a broad range of applications for these products:

- Alginate dressings are used on wounds that exude moderate to heavy amounts of fluid. They are useful for packing wounds, although strip-packing gauze may be preferable for deeper wounds because it is easier to retrieve. Common applications of alginate dressings include treatment of acute surgical wounds, leg ulcers, sinuses, and pressure sores. These dressings should not be used on third-degree burns or wounds that are dry or are secreting only small amounts of fluid, because their powerful absorbing capability may dry out the wound. These are primary dressings that need be covered by a secondary dressing.
- Biosynthetic dressings are used on burns and other wounds. Another application is as a temporary dressing for skin autograft sites. Some persons may be allergic to these dressing materials.
- Collagen dressings are believed to hasten wound repair and are often used on stubborn wounds. They are most effective on wounds that contain no dead tissue. Collagen dressings should not be used on dry wounds, third-degree burns, or on any patient who is sensitive to bovine (cow) products.

- Composite dressings are sometimes used alone, sometimes in combination with other dressings. Deep wounds should first be packed with wound-filler material. These dressings should not be cut, and are not recommended for use on third-degree burns.
- Contact layers are designed for use in clean wounds that contain no dead tissue. They are not recommended for infected, shallow, dry, or infected wounds, or on third-degree burns.
- Gauze is used to pack wounds, and also for debridement and wicking. It is especially desirable for packing deep wounds. When using gauze to pack wounds, a loose packing technique is preferred.
- Growth factors. These have highly specific applications against such conditions as diabetic foot ulcers involving disease of the peripheral nerves. Growth factors are heat sensitive and often require refrigeration. These are not recommended for persons with benign or malignant tumors.
- Hydrocolloid dressings are used for leg ulcers, minor burns, pressure sores, and traumatic injuries. Because they are not painful to remove, hydrocolloid dressings are often employed in pediatric wound management. Because of their absorbent capabilities, they are used on wounds that are secreting light to moderate amounts of fluid.
- Hydrofibers are highly absorbent, so they are particularly useful for wounds that are draining heavily. For this reason, they are not recommended for dry wounds or wounds with little secretion, because they may result in dehydration. Hydrofibers should not be used as surgical sponges or on third-degree burns.
- Hydrogels are often used on wounds that contain dead tissue, on infected surgical wounds, and on painful wounds. They should not be used on wounds with moderate to heavy secretions. As with all dressings, it is important to check and follow the directions of the manufacturer. In the case of hydrogels, directions on some products indicate they are not to be used on third-degree burns.
- Hydropolymers are typically used on wounds with minimal to moderate drainage. They are not indicated for dry wounds or third-degree burns.
- Leg compression/wrapping products are used to increase blood flow and reduce edema in the lower extremities of the body. A medical doctor should be consulted before using these products on people with edema. In many cases, topical dressings are used under these products.
- Polyurethane foam dressings are very absorbent and are typically used on wounds with moderate to heavy secretions. They should not be used on third-degree burns or on wounds that are not draining or that have sinuses or tunneling.
- Skin substitutes are a relatively new product category, approved for treating venous leg ulcers. It is often advisable to cut slits in the artificial skin, so that wound secretions underneath do not lift the newly applied skin.
- Superabsorbents are employed on wounds that are secreting heavily, or in applications requiring extended wear. A packing material is commonly employed under this product. Superabsorbents should not be used on third-degree burns or wounds that are either dry or have minimal secretions.
- Transparent films are often employed as a secondary cover for another, primary dressing. They are used on superficial wounds and on intact skin at risk of infection. It is important to remove transparent films very carefully to avoid damaging fragile skin.
- Wound fillers are primary dressings that are usually used in conjunction with other, secondary dressings. Wound fillers are considered appropriate for shallow wounds with little or moderate secretions. They are not appropriate for use in third-degree burns or in dry wounds. They are similarly not recommended for wounds with tunnels or sinuses.
- Wound pouches are useful in treating wounds with high volumes of secretion. They are not suitable for dry wounds.

Recommended intervals between dressing changes vary widely among product classes. The materials used in some dressings require that they be changed several times a day. Others can remain in place for one week. Manufacturer's directions should be consulted and followed.

Preparation

Wounds require appropriate cleaning, **debridement**, closure, and medication before bandages and dressings are applied.

Determining the cause of wounds is often very important, especially the cause of chronic wounds such as skin **ulcers**. A physician should be advised of any signs of infection or other changes in a wound. Signs of infection may include redness around the wound site, **fever**, red streaks extending from the wound, yellow drainage from the wound, or a mal odor noted at the wound site.

Wound-care nursing is a rapidly advancing field that requires considerable training, clinical experience, and judgment, causing some observers to predict that it will eventually develop into an advanced

WWW.BOOKBAZ.IR

KEY TERMS

Debridement—Removing dead or nonviable tissue from a wound.

Edema—Swelling of body tissues, caused by the collection of excess fluid.

Electrotherapy—The treatment of body tissues by passing electrical currents through them, stimulating the nerves and muscles.

Sinus—In the context of wound management, a narrow hollow in the body extending from an infected area to the surface of the skin.

Stockinette—A soft elastic material used for bandages and clothing for infants.

practice nursing or a specialty-based practice. Increasingly, the demands on wound-care nurses are expected to require that they undertake graduate studies. For all nurses working in the field, ongoing education is a must to keep up with new knowledge, technologies, and techniques. Numerous organizations and institutions offer continuing education courses in wound care management.

Results

Wounds that receive appropriate and timely care are most likely to heal in an acceptable manner.

Bang's disease *see* **Brucellosis**

Barbiturate-induced coma

Definition

A barbiturate-induced **coma**, or barb coma, is a temporary state of unconsciousness brought on by a controlled dose of a barbiturate drug, usually pentobarbital or thiopental.

Purpose

Barbiturate comas are used to protect the brain during major brain surgery, such as the removal of **arteriovenous malformations** or aneurysms. Coma may also be induced to control intracranial **hypertension** caused by brain injury.

Precautions

Barbiturate-induced comas are used when conventional therapy to reduce intracranial hypertension has failed. Barbiturate dosing is geared toward burst

KEY TERMS

Aneurysm—A bulge or sack-like projection from a blood vessel.

Arteriovenous malformation—An abnormal tangle of arteries and veins in which the arteries feed directly into the veins without a normal intervening capillary bed.

Diuretic agent—A drug that increases urine output.

Electroencephalography—The recording of electrical potentials produced by the brain. These potentials indicate brain activity.

Hyperventilation—A respiratory therapy involving deeper and/or faster breathing to keep the carbon dioxide pressure in the blood below normal.

Intracranial hypertension—Abnormally high blood pressure within the skull.

Osmotherapy—Intravenous injection or oral administration of an agent that induces dehydration. The goal of dehydration is to reduce the amount of accumulated fluid in the brain.

Steroid—A type of drug used to reduce swelling.

suppression—that is, reducing brain activity as measured by **electroencephalography**. This reduction in brain activity has to be balanced against the potential side effects of **barbiturates**, which include allergic reactions and effects on the cardiovascular system.

Description

One of the greatest hazards associated with brain injury is intracranial hypertension. Brain injury may be caused by an accidental **head injury** or a medical condition, such as **stroke**, tumor, or infection. When the brain is injured, fluids accumulate in the brain, causing it to swell. The skull does not allow for the expansion of the brain; in effect, the brain becomes compressed.

If the pressure does not abate, oxygenated blood may not reach all areas of the brain. Also, the brain tissue may be forced against hard, bony edges on the interior of the skull. In either case, the brain tissue may die, causing permanent brain damage or death.

Barbiturates reduce the metabolic rate of brain tissue, as well as the cerebral blood flow. With these reductions, the blood vessels in the brain narrow, decreasing the amount of swelling in the brain. With the swelling relieved, the pressure decreases and some or all brain damage may be averted.

Controversy exists, however, over the benefits of using barbiturates to control intracranial hypertension. Some studies have shown that barbiturate-induced coma can reduce intracranial hypertension but does not necessarily prevent brain damage. Furthermore, the reduction in intracranial hypertension may not be sustained.

Preparation

Inducing a barbiturate coma is usually kept in reserve for cases in which conventional treatments for controlling intracranial hypertension have failed. Before coma is induced, intracranial hypertension may be treated by hyperventilation; by facilitation of blood flow from the brain; by decompressive surgical procedures, such as draining excess fluids from under the skull or from the chambers within the brain (ventricles); or by drug therapy, including osmotherapy, diuretic agents, or **steroids**.

Risks

An estimated 25% of barbiturate-induced comas are accompanied by severe side effects. The side effects of barbiturates, especially the depressive effect on the cardiovascular system, can be too risky for some patients. Other side effects include impaired gastrointestinal motility and impaired immune response and infection. Since barbiturates depress activity in the brain, measurements of brain activity may be unreliable. Careful monitoring of the patient is required to ensure nutritional needs are being met and to guard against complications, such as lung infection, fevers, or deep vein **blood clots**.

Results

In many patients who do not respond to conventional therapy, barbiturate-induced coma can achieve the necessary control of intracranial hypertension.

Barbiturates

Definition

Barbiturates are mood-altering, central nervous system depressant medicines.

Purpose

Also known as sedative-hypnotic drugs, barbiturates make people relaxed, calm, and sleepy. They are sometimes used to control seizures (convulsions) and to produce **coma** following **head injury** or brain surgery.

These medicines are habit forming and should be used for only short periods of time to treat **anxiety** or sleeplessness.

Description

Barbiturates are available only with a physician's prescription and are sold in capsule, tablet, liquid, and injectable forms. Some commonly used barbiturates are phenobarbital, secobarbital (Seconal), pentobarbital (Nembutal), and amobarbital (Amytal).

Recommended dosage

Recommended dosage depends on the barbiturate used and other factors such as the patient's age and the condition for which the medicine is being taken. Check with the physician who prescribed the drug or the pharmacist who filled the prescription for the correct dosage.

Precautions

Always take barbiturates as directed. Never take larger or more frequent doses.

Barbiturates may add to the effects of alcohol and other drugs that produce drowsiness or depress the central nervous system, like **antihistamines**, cold medicines, over-the-counter sleep aids, medicine for seizures or convulsions, tranquilizers, **pain** relievers, and **muscle relaxants**.

People who have been taking barbiturates for long periods of time should not stop taking them suddenly, as they may develop withdrawal symptoms like nervousness, or even convulsions. These medicines should be discontinued gradually.

Taking an overdose of barbiturates or combining barbiturates with alcohol or other **central nervous system depressants** can cause unconsciousness and even death. Anyone who shows signs of an overdose or a reaction to combining barbiturates with alcohol or other drugs should get emergency medical help. Signs of overdose include:

- severe drowsiness
- shallow or slow breathing
- slurred speech
- loss of balance or staggering gait
- slow heartbeat and low blood pressure
- confusion
- generalized weakness

Barbiturates may change the results of certain medical tests. Before having medical tests, anyone taking these drugs should alert the healthcare professional in charge.

Drowsiness, lightheadedness or lack of muscular coordination from barbiturates can last many hours. Anyone who takes these drugs should not drive or use potentially dangerous machines until they find out how the drugs affect them.

Barbiturates may cause physical or mental dependence when taken over long periods of time. Signs of dependence include:

- the need to take increasing doses of the medicine to get the same effect
- a strong desire to keep taking the medicine
- withdrawal symptoms, such as anxiety, nausea or vomiting, convulsions, trembling, or sleep problems when the medicine is stopped

Children, older adults, or people who are seriously ill may be especially sensitive to the effects of barbiturates, increasing the risks of confusion, drowsiness, or even excitement.

ALLERGIES. Anyone who has had unusual reactions to barbiturates in the past should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. Taking barbiturates during **pregnancy** increases the chance of **birth defects** and may cause other problems such as prolonged labor and withdrawal effects in babies following birth. Pregnant women who must take barbiturates for serious or life-threatening conditions should thoroughly discuss with their physicians the benefits and risks of taking this medicine.

BREASTFEEDING. Barbiturates pass into breast milk and may cause problems such as drowsiness, breathing problems, or slow heartbeat in nursing babies whose mothers take the medicine.

KEY TERMS

Adrenal glands—Two glands located next to the kidneys. The adrenal glands produce the hormones epinephrine and norepinephrine and the corticosteroid (cortisone-like) hormones.

Anemia—A lack of hemoglobin, the compound in blood that carries oxygen from the lungs throughout the body and brings waste carbon dioxide from the cells to the lungs, where it is released.

Central nervous system—The brain and spinal cord.

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

Hypnotic—A medicine that causes sleep.

Porphyria—A disorder in which porphyrins build up in the blood and urine.

Porphyrin—A group of organic compounds such as chlorophyll, which makes plants green, and hemoglobin, which makes blood red.

Sedative—Medicine that has a calming effect and may be used to treat nervousness or restlessness.

Seizure—A sudden attack, spasm, or convulsion.

Withdrawal symptoms—A group of physical or mental symptoms that may occur when individuals suddenly stop using a drug to which they have become dependent.

OTHER MEDICAL CONDITIONS. Before using barbiturates, people with any of these medical problems should make sure their physicians are aware of their conditions:

- alcohol or drug abuse
- depression
- hyperactivity (in children)
- pain
- kidney disease
- liver disease
- diabetes
- overactive thyroid
- underactive adrenal gland
- chronic lung diseases such as asthma or emphysema
- severe anemia
- acute, intermittent porphyria

USE OF CERTAIN MEDICINES. Taking barbiturates with certain other drugs may affect the way the drugs work or may increase the chance of side effects from either or both drugs.

Side effects

The most common side effects are **dizziness**, lightheadedness, drowsiness, and clumsiness or unsteadiness. These problems usually go away as the body adjusts to the drug and do not require medical treatment unless they persist or interfere with normal activities.

More serious side effects are not common, but may occur. If any of the following side effects occur, check with the physician who prescribed the medicine immediately:

- slow pulse or low blood pressure
- fainting
- fever
- muscle or joint pain
- sore throat
- tightness in the chest or chest pain
- wheezing
- skin problems such as rash, hives, or red, thickened, or scaly skin
- bleeding sores on the lips
- sores or painful white spots in the mouth
- swollen eyelids, face, or lips

In addition, check with a physician as soon as possible if confusion, depression, or unusual excitement occur after taking barbiturates.

Patients who take barbiturates for a long time or at high doses may notice side effects for some time after they stop taking the drug. These effects usually appear within 8–16 hours after the patient stops taking the medicine. Check with a physician if these or other troublesome symptoms occur after stopping treatment with barbiturates:

- dizziness, lightheadedness, or faintness
- anxiety or restlessness
- hallucinations
- vision problems
- nausea and vomiting
- seizures (convulsions)

WWW.BOOKBAZ.IR

- muscle twitches or trembling hands
- weakness
- sleep problems, nightmares, or increased dreaming

Other side effects may occur. Individuals who have unusual symptoms during or after treatment with barbiturates should get in touch with their physician.

Interactions

Birth control pills may not work properly when taken while barbiturates are being taken. To prevent pregnancy, use additional methods of birth control while taking barbiturates.

The drugs that may interact with barbiturates include:

- Medicines that depress the central nervous system, such as those used for treating allergies, colds, or hay fever, as well as sedatives, tranquilizers, pain medicines, muscle relaxants, and over-the-counter sleep aids.
- Barbiturates reduce the effects of warfarin (Coumadin).
- The effects of beta-adrenergic blocking drugs like metaprolol (Lopressor) and propanalol (Inderal) are reduced by barbiturates.
- Barbiturates reduce the effects of antipsychosis drugs like clozapine (Clozaril).
- The effects of adrenocorticoid steroid medications, like cortisone, are reduced by barbiturates.
- Antiseizure medicines such as valproic acid (Depakote and Depakene) and carbamazepine (Tegretol) may increase the effects of barbiturates.
- Barbiturates may reduce the effectiveness of tetracycline antibiotics.
- The effects of felodipine (Plendil) may be decreased by barbiturates.
- Phenobarbital may decrease the effectiveness of drugs taken internally to treat fungal infections, like griseofulvin (Grifulvin). Separating the time of administering the drugs may help reduce this effect.
- Barbiturates may reduce the effectiveness of nifedipine (Procardia).
- Barbiturates may reduce the effectiveness of quinidine.
- Barbiturates may reduce the effectiveness of aminophylline used to treat asthma.

Barbiturates may also interact with other medicines. When this happens, the effects of one or both drugs may change or the risk of side effects may be increased. Anyone who takes barbiturates should let the physician know all other medicines he or she is taking.

The list above does not include every drug that may interact with barbiturates. Be sure to check with a physician or pharmacist before combining barbiturates with any other prescription or nonprescription (over-the-counter) medicine.

Bariatric surgery

Definition

Bariatric surgeries are surgical weight-loss procedures that reduce or bypass the stomach or small intestine so that severely overweight people can achieve significant and permanent weight loss.

Description

Weight loss through surgery can be achieved either by operations that restrict the amount of food the stomach can hold (restrictive surgery), reduce the amount of nutrients that are absorbed (malabsorptive surgery), or some combination of the two. Both approaches are used in the United States, each with its advantages and disadvantages.

Bariatric surgery usually is performed in a hospital by a surgeon who has experience with **obesity** surgery or at a center that specializes in the procedure. General **anesthesia** is used, and the operation takes 2–3 hours. The hospital stay lasts about a week. In all weight-loss surgeries, the experience and skill of the surgeon affects the success of the procedure. Individuals should select a surgeon and hospital with this in mind.

Healthcare insurers vary in whether they consider bariatric surgery elective surgery and may or may not cover it under their policies. If they do cover weight-loss surgery, extensive documentation of the necessity for surgery may be required. Approval from the insurer should be sought before this operation is performed.

Restriction Surgery

Restriction surgery is the most common type of bariatric surgery performed in the United States. The normal, unrestricted stomach can hold about 6 cups (48 oz. or 1.5 L) of food. With restriction surgery, the capacity of the stomach is reduced to about 1–3 oz. (30–90 mL). Adjustable gastric band, or Lap-Band surgery, achieves restriction by placing a saline (salt water) filled bag around the stomach, pinching off a portion of it, and leaving only a small pouch at the top. The exit to the pouch is narrowed so that the rate at which the pouch empties may be slowed. Because the pouch is so small, the individual can only eat about half a cup of food at a time without feeling nauseated.

Advantages of the adjustable gastric band are as follows:

- This is the safest surgical weight-loss procedure.
- Recovery time is rapid compared to other weight-loss surgeries.
- A port in the skin allows access to the saline bag. The size of the stomach pouch opening can be adjusted without additional surgery by adjusting the pressure in the saline band.
- No part of the digestive system is removed; digestion continues normally just with much smaller amounts of food.
- People having this surgery do not feel hungry because stretch sensors in the wall of the stomach tell the brain that the stomach is full.
- Weight loss averages 40–50% of the excess body weight during the first two years.
- Obesity-related health problems are substantially reduced as weight is lost.
- The band can be removed. The surgery is reversible because no part of the digestive system was changed.
- The procedure is often covered by Medicare.

Disadvantages of the adjustable gastric band are:

- Individuals must relearn how to eat. The band requires that they eat five or six very small meals a day. They will vomit if too much food is consumed at once.
- The individual must learn to chew food well, eat slowly, and drink liquids between rather than with meals.
- There is a small risk that the band will slip and additional surgery will be required to fix or remove it.
- The individual must commit to eating a healthy diet in order to maintain weight loss. High-calorie foods such as milkshakes can cause weight gain; weight loss is less than with malabsorptive surgeries.

A second type of restrictive surgery is **vertical banded gastroplasty** (VBG), also known as stomach stapling. This surgery is performed less often than Lap-Band surgery. With VBG, part of the stomach is stapled and banded shut, making it smaller, so that individuals feel full sooner. The advantage of VBG is that the procedure is quick and has few complications. Disadvantages are that average weight loss is less than with other weight-loss surgeries, and staples can pull out allowing small leaks between the stomach and the abdomen to develop. Infection is possible, but rare (less than 1%). This procedure is usually not covered by Medicare.

A third restrictive surgery is vertical sleeve **gastrectomy** (VSG), also called sleeve gastrectomy, vertical gastrectomy, greater curvature gastrectomy, parietal gastrectomy, and longitudinal gastrectomy. In this procedure, a portion of the stomach is surgically removed, and the remainder of the stomach remains attached to the small intestine.

This procedure may be considered as an alternative for morbidly obese individuals whose health does not permit them to safely undergo Roux-en-Y malabsorption surgery. Advantages of this surgery are that it permanently removes a portion of the stomach that produces ghrelin, an appetite-stimulating hormone. In addition, the capacity of the stomach is reduced to about one ounce, and nutrient absorption problems are less likely to occur because the stomach continues to be normally connected to the small intestine; no part of the intestine is bypassed. Disadvantages of this surgery are part of the stomach is permanently removed so it is not a reversible procedure, the part of the stomach that remains can stretch, allowing greater food capacity with the risk of weight gain, and there is a greater chance of long-term vitamin deficiencies.

Intragastric balloon placement is a fourth type of restriction technique, although it technically is not bariatric surgery. The procedure is available in Europe, South America, Mexico, Canada, and Australia. As of 2014, it was not available in the United States. This procedure involves placing a silicon balloon in the stomach and inflating it to fill up part of the stomach so that the individual feels full sooner. An advantage of the intragastric balloon is that it can be placed in the stomach and removed without surgery. Intragastric balloons are intended for temporary use (about 6 months) and are for use in conjunction with a managed program of weight control.

Malabsorptive surgery

Malabsorptive surgery, also called **gastric bypass** surgery, creates an alternate route for food through

WWW.BOOKBAZ.IR

the digestive system so that the food bypasses part of the intestine and fewer nutrients are absorbed. In practice, malabsorptive surgery is combined with some type of restrictive surgery so that less food is also moving through the digestive tract.

The most common type of gastric bypass surgery is Roux-en-Y gastric bypass. In this surgery, a small stomach pouch is created by stapling and banding the stomach. Next, a Y-shaped piece of intestine is attached to the pouch on one end, and the jejunum, or second part of the small intestine, on the other. This allows food to bypass the duodenum, or first part of the intestine where many calories and nutrients are absorbed. The food then continues normally through the rest of the small intestine and the large intestine.

The great advantage of Roux-en-Y gastric bypass is that individuals lose on average 60–70% of their excess weight and are able to maintain the weight loss for 10 years or more. As a result, most obesity-related health problems are substantially reduced or cured when weight is lost and weight loss maintained. In the United States Medicare often will pay for this surgery.

Roux-en-Y surgery has some serious disadvantages. These are as follows:

- This surgery is more difficult for the surgeon than restrictive surgeries and involves permanently altering the digestive system.
- Many vitamins and minerals are absorbed in the part of the small intestine bypassed by this surgery. The individual must commit to a lifetime of taking nutritional supplements to prevent serious vitamin and mineral deficiencies.
- Tearing, bleeding, and infection at the sites where the cuts and reconnections were made are potentially fatal complications.
- Dumping syndrome may occur in response to meals high in sugar. Dumping occurs when food moves too fast through the intestine and causes symptoms of nausea, bloating, weakness, sweating, fainting, and diarrhea.

Billopancreatic diversion (BPD), another type of malabsorptive surgery, bypasses an even longer section of the small intestine. In BPD, about two-thirds of the stomach is surgically removed, leaving a pouch that can hold about 3 cups of food. A bypass is then created to the ileum, or final portion of the small intestine. In all, about 9 ft (3 m) of intestine are bypassed. As a result, fewer calories and nutrients are absorbed. The main advantage of BPD is the large amount of excess weight—between 75% and 80%—that is lost over the first two years and the health benefits that this loss brings. In the United States, Medicare will often pay for this surgery.

Disadvantages are the same as for Roux-en-Y surgery, but nutrient deficiencies are greater. Because fat is poorly digested as a result of this surgery, bowel movements are frequent and stools are especially foul smelling.

Purpose

Obesity is the second leading cause of preventable death in the United States. It is linked to an increased likelihood of developing over 20 different diseases and disorders, including high blood pressure (**hypertension**), type 2 diabetes, **heart disease**, **stroke**, deep vein **blood clots**, fatty **liver disease**, **sleep apnea**, **heartburn**, **gastroesophageal reflux disease** (GERD), gallstone disease, arthritis, **colon cancer**, breathing problems, and depression. According to the National Institutes of Health, in 2012, 36.1% of Americans were overweight and an additional 26.2% were obese and 4% were severely or morbidly obese.

Obesity is defined by the **body mass index** (BMI). This calculation compares weight to height. Adults age 20 and older are evaluated as follows:

- BMI below 18.5: Underweight
- BMI 18.5–24.9: Normal weight
- BMI 25.0–29.9: Overweight
- BMI 30 and above: Obese
- BMI 40 and above: Morbidly or severely obese

Bariatric surgery is performed only on severely overweight people who have a BMI of 40 or greater or who are at least 100 pounds over their ideal weight. This level of obesity is often referred to as morbid obesity as it can result in many serious, and potentially deadly, health problems. Adjustable gastric band bariatric surgery is also approved for individuals with a BMI of 30 or greater and who have a health problem such as diabetes or heart disease associated with obesity. Bariatric surgery is performed only on people whose risk of complications from surgery is outweighed by the need to lose weight to prevent health complications and for whom supervised weight-loss and **exercise** programs have repeatedly failed. Bariatric surgery, however, does not make people thin. Most people lose about 60% of their excess weight through this treatment. Changes in diet and exercise are still required to maintain a normal weight.

Precautions

Bariatric surgery should not be performed unless a patient meets the following criteria:

- has a BMI of 40 or above or BMI of 30 or above and is at high risk for serious obesity-related health problems

KEY TERMS

Fat-soluble vitamin—A vitamin that dissolves in and can be stored in body fat or the liver.

Gastroesophageal reflux disease (GERD)—A condition in which gastric juice from the stomach backs up into the bottom of the esophagus and causes irritation, inflammation, or erosion of the cells lining the esophagus.

Heartburn—A pain in the center of the chest behind the breastbone caused by the contents of the stomach backflowing (refluxing) into the lower end of the esophagus and causing irritation.

Mineral—An inorganic substance found in the earth that is necessary in small quantities for the body to maintain health. Examples are zinc, copper, and iron.

Morbidly obese—Defines a person who is 100 lb (45 kg) (or more than 50%) overweight and has a body mass index above 40.

Osteoporosis—A condition found in older individuals in which bones decrease in density and become fragile and more likely to break. It can be caused by lack of vitamin D and/or calcium in the diet.

Sleep apnea—A sleep disorder in which breathing stops briefly then resumes on its own. These pauses can occur many times each night, resulting in poor quality of sleep.

Type 2 diabetes—Sometimes called adult-onset diabetes, a disease that prevents the body from properly using glucose (sugar) but can often be controlled with diet and exercise.

Vitamin—A nutrient that the body needs in small amounts to remain healthy but that the body cannot manufacture for itself and must acquire through diet.

- has been unsuccessful in serious attempts lose weight
- is well-informed and has realistically considered the risks and benefits of the procedure
- has made a commitment to the lifelong changes in eating habits that are required after surgery
- will keep follow-up and nutritional counseling appointments; understands that lifelong medical follow-up is likely to be necessary
- has met with a psychologist or psychiatrist and is emotionally stable

Bariatric surgery is not appropriate for people who have substance addictions or who have psychological disorders. Other considerations in choosing candidates for obesity surgery include the person's general health and willingness to comply with follow-up treatment.

There is some controversy about performing bariatric surgery on children. As of 2014, the surgery was performed only if the child had a BMI of 40 or greater, had seriously tried to lose weight for 6 or more months and been unsuccessful, has reached his or her full adult height (usually in early to mid teens), has serious health problems relate to obesity, and is emotionally mature enough to understand and comply with the eating restrictions and psychological changes that accompany bariatric surgery.

Preparation

After patients are carefully selected as appropriate for obesity surgery, they receive standard preoperative blood and urine tests and meet with an anesthesiologist to discuss how their health may affect the administration of anesthesia. Pre-surgery counseling is required to help patients anticipate what to expect after the operation. Patients are also frequently asked to lose weight before surgery.

Aftercare

Immediately after the operation, most patients are restricted to a liquid diet for 2–3 weeks; however, some may remain on it for up to 12 weeks. Patients then move on to a diet of pureed food for about a month, and after about two months most can tolerate solid food.

Restrictive surgeries pose few special nutritional concerns, but malabsorptive surgeries require both a specialized diet for several months after surgery and a lifelong commitment to taking **nutritional supplements**. Individuals having bariatric surgery receive both psychological and nutritional counseling before and after surgery.

Post-surgical recovery diet

After gastric bypass or BPD, the individual does not eat anything for one or two days, giving the bowel time to rest. During this time, all **nutrition** is given intravenously. Once individuals begin eating, they follow a schedule similar to the one below:

- Liquids such as juice, broth, milk, or diluted cooked cereal for two or three days.

WWW.BOOKBAZ.IR

- Pureed foods that have the texture of baby food for two or three weeks while the stomach heals. These foods must be smooth and contain no chunks.
- Soft foods such as ground meat and soft-cooked fruits and vegetables for about eight weeks.
- Regular food can be eaten in very small amounts. Most people begin by eating six tiny meals a day. These meals should be high in protein. Food must be chewed thoroughly. Liquids are drunk between meals, not with them. Vitamin and mineral supplements are essential.

Lifelong nutritional supplementation

People who have gastric bypass surgery or BPD need extensive nutritional counseling and must take vitamin and mineral supplements for the rest of their lives. Most iron and **calcium** is absorbed in the duodenum, the first part of the intestine that is bypassed by these operations. Calcium deficiency can lead to **osteoporosis**, and iron deficiency can cause anemia.

In BPD, only 25% of the fat in food is absorbed because so much of the small intestine is bypassed. The fat-soluble **vitamins** A, D, E, and K are absorbed along with fat. When the body absorbs too little fat, inadequate amounts of these fat-soluble vitamins are absorbed, so dietary supplements containing these vitamins must be taken. Other vitamins that may not be absorbed in adequate amounts are vitamin B12, folate, and vitamin B1 (thiamine). Research found that a very small number of people developed a brain disorder called Wernicke **encephalopathy** 4–12 weeks after bariatric surgery. This disorder is caused by a deficiency of vitamin B1. Most of the people who develop the disorder have failed to take their vitamin supplements as prescribed after surgery.

Patients are expected to work on changing their eating and exercise habits to assist in weight loss. Most people eat 3–4 small meals a day once they return to solid food. Eating too quickly or too much after obesity surgery can cause **nausea and vomiting** as well as intestinal "dumping," a condition in which undigested food is shunted too quickly into the small intestine, causing **pain**, **diarrhea**, weakness, and **dizziness**.

Results

Most people who have surgery for obesity lose anywhere from 40–80% of their excess weight depending on the procedure chosen, compliance with diet, and general activity level. However, quite a few put pounds back on beginning several years after surgery. The main reason for weight gain is noncompliance with nutrition and exercise plans. Also, over time the size of the stomach pouch in restrictive surgeries tends to stretch, allowing people to eat more and still feel comfortable. On the positive side, people who lose weight through surgery almost always see great improvement in any obesity-related diseases they have.

Weight-loss surgery does have some serious risks. Complications include slipping of the band in gastric band surgery, failure of the staples in VBG, infection, dumping syndrome in malabsorptive surgery, and an increased risk of **gallstones** and abdominal hernias. The risk of death is less than 1% in gastric bypass surgery and 2.5–5% in BPD. About 20% of people who have VBG surgery need a second operation to correct problems arising from the procedure. **Pregnancy**, although possible, also presents some special nutritional risks to women who have had weight loss surgery. Bariatric surgery is not a magic weight-loss operation, and success also depends on the patient's willingness to exercise and eat low-calorie foods. When deciding whether to have a surgical weight-loss procedure, the expected benefits must outweigh the risks of continued obesity.

Risks

As in any abdominal surgery, there is always a risk of excessive bleeding, infection, and allergic reaction to anesthesia. Specific risks associated with obesity surgery include leaking or stretching of the pouch and loosening of the gastric staples. Although the average death rate associated with this procedure is less than 1%, the rate varies from center to center, ranging from 0–4%. Long-term failure rates can reach 50%, sometimes making additional surgery necessary. Other complications of obesity surgery include intolerance to foods high in fats, **lactose intolerance**, bouts of **vomiting**, diarrhea, and intestinal discomfort

Studies suggest that gastric bypass surgery complications increase with age, weight, and male gender. Patients age 55 and older experience more complications than younger patients, and male patients are more likely to have life-threatening complications than female patients, particularly those who were more severely obese.

Barium enema

Definition

A barium enema, also known as a lower GI (gastrointestinal) exam, is a test that uses x-ray examination to view the large intestine, including the colon and rectum. There are two types of tests: the single-contrast technique, where barium sulfate is injected into the rectum to gain a profile view of the large intestine, and the double-contrast (or "air contrast") technique, where air and barium are inserted into the rectum.

Purpose

A barium enema may be performed for a variety of reasons. One reason may be to help in the diagnosis of colon and **rectal cancer** (or colorectal cancer) and inflammatory disease. Detection of polyps (benign growths in the tissue lining the colon and rectum), diverticula (pouches pushing out from the colon), and structural changes in the large intestine can also be confirmed by a barium enema. The double-contrast barium enema is the best method for detecting small tumors (such as polyps), early inflammatory disease, and bleeding caused by **ulcers**. The test is also used to detect Crohn's disease.

A doctor's decision to perform a barium enema is based on a patient's history of altered bowel habits. These can include **diarrhea**, **constipation**, lower abdominal **pain**, or patient reports of blood, mucus, or pus in the stools. It is recommended that healthy people have a colorectal cancer screening **colonoscopy** every five to ten years, because this form of cancer is the second most deadly type in the United States. People who have a close relative with colorectal cancer or have had a precancerous polyp are considered to be at an increased risk for the disease and should be screened more frequently by their doctor for possible abnormalities. Colonoscopies are done more often now than barium enema tests.

Description

A barium enema exam does not require **sedation**. To begin a barium enema, the doctor will have a patient lie down on a tilting radiographic table so that x rays of the abdomen can be taken. The film is then reviewed by a radiologist, who assesses if the colon has been adequately cleansed of stool during the prep process. After the patient is moved into a different position, a well-lubricated rectal tube is inserted through the anus. This tube allows the physician or the assisting healthcare provider to slowly administer the barium into the intestine. While this filling process is closely monitored, the patient must keep the anus tightly contracted against the rectal tube so that the position is maintained and the barium is prevented from leaking. This step is emphasized to the patient, because inaccuracies may occur if the barium leaks. A rectal balloon may also be inflated to help the patient retain the barium. The table may be tilted or the patient may be moved to different positions to aid in the filling process.

As the barium fills the intestine, x rays of the abdomen are taken to distinguish significant findings. There are many ways to perform a barium enema. One way is that shortly after filling, the rectal tube is removed and the patient expels as much of the barium as possible. Alternatively, the tube will remain in place, and the barium will move through that tube. A thin film of barium remains in the intestine, and air is then slowly injected through the rectum to expand the bowel lumen. Usually, no films will be taken until after the air is injected. Multiple films are generally obtained by a radiologist, then additional films are taken by a technologist.

WWW.BOOKBAZ.IR

Preparation

To conduct the most accurate barium enema test, the patient must follow a prescribed diet and **bowel preparation** instructions prior to the test. This preparation commonly includes restricted intake of dairy products and a liquid diet for 24 hours prior to the test, in addition to drinking large amounts of water or clear liquids 12–24 hours before the test. Patients may also be given **laxatives** and may be asked to give themselves a cleansing enema.

In addition to the prescribed diet and bowel preparation prior to the test, the patient can expect the following during a barium enema:

- They will be draped with a gown as they are placed on a tilting x-ray table.
- As the barium or air is injected into the intestine, they may experience cramping pains or the urge to defecate.
- The patient will be instructed to take slow, deep breaths through the mouth to ease any discomfort.

Aftercare

Patients should follow several steps immediately after undergoing a barium enema, including:

- Drinking plenty of fluids to help counteract the dehydrating effects of bowel preparation and the test.
- Taking time to rest; a barium enema and the bowel preparation taken before it can be exhausting.
- A cleansing enema may be given to eliminate any remaining barium. Lightly colored stools will be prevalent for the next 24–72 hours following the test.

Risks

While a barium enema is considered a safe screening test used on a routine basis, it can cause complications in certain people. The following indications should be kept in mind before a barium enema is performed:

- People who have a rapid heart rate, severe ulcerative colitis, toxic megacolon, or a presumed perforation in the intestine should not undergo a barium enema.
- The test can be performed cautiously if the patient has a blocked intestine, ulcerative colitis, diverticulitis, or severe bloody diarrhea.
- Complications that may be caused by the test include perforation of the colon, water intoxication, barium granulomas (inflamed nodules), and allergic reactions. However, these conditions are all very rare.

KEY TERMS

Barium sulfate—A barium compound used during a barium enema to block the passage of x rays during the exam.

Biopsy—The removal of a sample of tissue for examination under a microscope to check for cancer cells or other abnormalities.

Bowel lumen—The space within the intestine.

Colonoscopy—An examination of the colon performed with a colonoscope.

Diverticula—The plural form of diverticulum, a sac or pouch in the colon wall that is usually asymptomatic (without symptoms), but may cause difficulty if it becomes inflamed.

Diverticulitis—A condition of the diverticulum of the intestinal tract, especially in the colon, where inflammation may cause distended sacs extending from the colon and pain.

Diverticulosis—The development of diverticula.

Megacolon—Abnormally large colon associated with some chronic intestine disorders.

Proctosigmoidoscopy—A visual examination of the rectum and sigmoid colon using a sigmoidoscope, also known as sigmoidoscopy.

Sigmoidoscopy—Endoscopic examination of the lower colon.

Ulcerative colitis—An ulceration or erosion of the lining of the colon.

Results

When patients undergo single-contrast **enemas**, their intestines are steadily filled with barium to differentiate markings of the colon. Normal results display uniform filling of the colon.

As the barium is expelled, the intestinal walls collapse. A normal result on the x ray after defecation will show the intestinal lining as having a standard, feathery appearance.

The double-contrast enema expands the intestine, which is already lined with a thin layer of barium, using air to display a detailed image of the mucosal pattern. Varying positions taken by the patient allow the barium to collect on the dependent walls of the intestine by way of gravity.

A barium enema allows abnormalities to appear on an x ray that may aid in the diagnosis of several

different conditions. Most colon cancers occur in the rectosigmoid region, or on the upper part of the rectum and adjoining portion of the sigmoid colon. However, they can also be detected with a proctosigmoidoscopy (usually referred to as a **sigmoidoscopy**). Further, an enema can identify other early signs of cancer.

Identification of polyps, **diverticulosis**, and inflammatory disease (such as **diverticulitis** and ulcerative **colitis**) is attainable through a barium x ray. Some cases of acute **appendicitis** may also be apparent by viewing this x ray, although acute appendicitis is usually diagnosed clinically or by a computed tomography (CT) scan.

Bartholin's gland cyst

Definition

A Bartholin's gland cyst is a swollen fluid-filled lump that develops from a blockage of one of the Bartholin's glands, which are small glands located on each side of the opening to the vagina. Bartholin's gland cysts and abscesses are commonly found in women of reproductive age, developing in approximately 2% of all women.

Description

The Bartholin's glands are located in the lips of the labia that cover the vaginal opening. The glands (normally the size of a pea) provide moisture for the vulva area. A Bartholin's gland cyst may form in the gland itself or in the duct draining the gland. A cyst normally does not cause **pain**, grows slowly, and may go away without treatment. It usually ranges in size from 0.4-1.2 in. (1–3 cm), although some may grow much larger.

If infected, a Bartholin's gland cyst can form an **abscess** that will increase in size over several days and is very painful. In order to heal, a Bartholin's gland cyst usually must be drained.

Causes and symptoms

A Bartholin's gland cyst occurs if the duct becomes blocked for any reason, such as infection, injury, or chronic inflammation. Very rarely a cyst is caused by cancer, which usually occurs only in women over the age of 40. In many cases, the cause of a Bartholin's gland cyst is unknown.

Symptoms of an uninfected Bartholin's gland cyst include a painless jump on one side of the vulva area (most common symptom) and redness or swelling in the vulva area.

Symptoms of an abscessed Bartholin's gland include:

- pain that occurs with walking, sitting, physical activity, or sexual intercourse
- fever and chills
- increased swelling in the vulva area over a two- to four-day period
- drainage from the cyst, normally occurring four to five days after the swelling starts

Abscesses may be caused by sexually transmitted bacteria, such as those causing chlamydial or gonococcal infections, while others are caused by bacteria normally occurring in the vagina. Over 60 types of bacteria have been found in Bartholin's gland abscesses.

Diagnosis

A Bartholin's gland cyst or abscess is diagnosed by a gynecological **pelvic exam**. If the cyst appears to be infected, a culture is often performed to identify the type of bacteria causing the abscess.

WWW.BOOKBAZ.IR

KEY TERMS

Marsupialization—Cutting out a wedge of the cyst wall and putting in stitches so the cyst cannot reoccur.

Sitz bath—A warm bath in which just the buttocks and genital area soak in water; used to reduce pain and aid healing in the genital area.

Window operation—Cutting out a large oval-shaped piece of the cyst wall and putting in stitches to create a window so the cyst cannot reoccur.

Word catheter—A small rubber catheter with an inflatable balloon tip that is inserted into a stab incision in the cyst, after the contents of the cyst have been drained.

Treatment

Treatment for this condition depends on the size of the cyst, whether it is painful, and whether the cyst is infected.

If the cyst is not infected, treatment options include:

- watchful waiting by the woman and her healthcare professional
- soaking of the genital area with warm towel compresses
- soaking of the genital area in a sitz bath
- use of nonprescription pain medication to relieve mild discomfort

If the Bartholin's gland is infected, there are several treatments available to treat the abscess, including:

- soaking of the genital area in a sitz bath
- treatment with antibiotics
- use of prescription or nonprescription pain medication
- incision and drainage; i.e., cutting into the cyst and draining the fluid (not usually successful, as the cyst often reoccurs)
- placement of a drain (Word catheter) in the cyst for two to four weeks so fluid can drain and prevent reoccurrence of the cyst
- marsupialization
- window operation
- use of a carbon dioxide laser to open the cyst and heat the cyst wall tissue so that the cyst cannot form a sac and reoccur
- incision and drainage, followed by treatment with silver nitrate to burn the cyst wall so the cyst cannot form a sac and reoccur
- removal of the entire Bartholin's gland cyst, if the cyst has reoccurred several times after use of other treatment methods

During surgical treatment, the area will be numbed with a local anesthetic to reduce pain. General **anesthesia** may be used for treatment of an abscess, as the procedure can be painful.

In a pregnant woman, surgical treatment of cysts that are asymptomatic should be delayed until after delivery to avoid the possibility of excessive bleeding. However, if the Bartholin's gland is infected and must be drained, **antibiotics** and local anesthesia are generally considered safe.

If the cyst is caused by cancer, the gland must be excised, and the woman should be under the care of a gynecologist familiar with the treatment of this type of cancer.

Alternatives

If a Bartholin's gland cyst has no or mild symptoms, or has opened on its own to drain, a woman may decide to use watchful waiting, warm sitz baths, and nonprescription pain medication. If symptoms become worse or do not improve, a healthcare professional should then be consulted.

Infected Bartholin's glands should be evaluated and treated by a healthcare professional.

Prognosis

A Bartholin's gland cyst should respond to treatment in a few days. If an abscess requires surgery, healing may take days to weeks, depending on the size of the abscess and the type of surgical procedure used. Most of the surgical procedures, except for incision and drainage, should be effective in preventing recurring infections.

Prevention

There are few ways to prevent the formation of Bartholin's gland cysts or abscesses. However, as a Bartholin's gland abscess may be caused by a sexually transmitted disease, the practice of **safe sex** is recommended. Using good hygiene (e.g., wiping front to

back after a bowel movement) is also recommended to prevent bacteria from the bowels from contaminating the vaginal area.

Bartonella bacilliformis infection

see **Bartonellosis**

Bartonellosis

Definition

Bartonellosis is an infectious bacterial disease with an acute form (which has a sudden onset and short course) and a chronic form (which has more gradual onset and longer duration). The disease is transmitted by sandflies and occurs in western South America. Characterized by a form of red blood cell deficiency (**hemolytic anemia**) and **fever**, the potentially fatal acute form is called Oroya fever or Carrion's disease. The chronic form is identified by painful **skin lesions**.

Description

The acute form of the disease gets its name from an outbreak that occurred in 1871 near La Oroya, Peru. More than 7,000 people perished. Some survivors later developed a skin disease, called verruga peruana (Peruvian **warts**). These skin lesions were observed prior to the 1871 outbreak—perhaps as far back as the pre-Columbian era—but a connection to Oroya fever was unknown. In 1885, a young medical researcher, Daniel Carrion, inoculated himself with blood from a lesion to study the course of the skin disease. When he became ill with Oroya fever, the connection became apparent. Oroya fever is often called Carrion's disease in honor of his fatal experiment.

The bacteria, *Bartonella bacilliformis*, was isolated by Alberto Barton in 1909, but was not identified as the cause of the fever until 1940. The *Bartonella* genus includes at least 11 bacteria species, four of which cause human diseases, including **cat-scratch disease** and **bacillary angiomatosis**. However, bartonellosis refers exclusively to the disease caused by *B. bacilliformis*. The disease is limited to a small area of the Andes Mountains in western South America; nearly all cases have been in Peru, Colombia, and Ecuador. A large outbreak involving thousands of people occurred in 1940–41, but bartonellosis has since occurred sporadically. Control of sandflies, the only known disease carrier (vector), has been credited with managing the disease.

Causes and symptoms

Bartonellosis is transmitted by the nocturnal sandfly and arises from infection with *B. bacilliformis*. The sandfly, *Lutzomyia verrucarum*, dines on human blood and, in so doing, can inject bacteria into the bloodstream. The sandfly is found only in certain areas of the Peruvian Andes; other, as-yet-unidentified vectors are suspected in Ecuador and Colombia.

Once in the bloodstream, the bacteria latch onto red blood cells (erythrocytes), burrow into the cells, and reproduce. In the process, up to 90% of the host's erythrocytes are destroyed, causing severe hemolytic anemia. The anemia is accompanied by high fever, muscle and joint **pain**, **delirium**, and possibly **coma**.

Two to eight weeks after the acute phase, an infected individual develops verruga peruana. However, individuals may exhibit the characteristic lesions without ever experiencing the acute phase. Left untreated, the lesions may last months or years. These lesions resemble blood-filled blisters, up to 1.6 in. (4 cm) in diameter, and appear primarily on the head and limbs. They can be painful to the touch and may bleed or ulcerate.

Diagnosis

Bartonellosis is identified by symptoms and the patient's history, such as recent travel in areas where bartonellosis occurs. Isolation of *B. bacilliformis* from the bloodstream or lesions can confirm the diagnosis.

Treatment

Antibiotics are the mainstay of bartonellosis treatment. The bacteria are susceptible to several antibiotics, including chloramphenicol, **penicillins**, and **aminoglycosides**. Blood transfusions may be necessary to treat the anemia caused by bartonellosis.

Prognosis

Antibiotics have dramatically decreased the fatality associated with bartonellosis. Prior to the development of antibiotics, the fever was fatal in 40% of cases. With antibiotic treatment, that rate has dropped to 8%. Fatalities can result from complications associated with severe anemia and secondary infections. Once the infection is halted, an individual can recover fully.

WWW.BOOKBAZ.IR

KEY TERMS

Acute—Referring to the course of a disease, or a phase of a disease, the short-term experience of prominent symptoms.

Chronic—Referring to the course of a disease, or a phase of a disease, the long-term experience of prominent symptoms.

Erythrocytes—Red blood cells.

Hemolytic anemia—A form of erythrocyte deficiency caused by the destruction of the red blood cells.

Host—The organism that harbors or nourishes another organism (parasite). In bartonellosis, the person infected with *Bartonella basilliformis*.

Vector—An organism, such as insects or rodents, that can transmit disease to humans.

Prevention

Avoiding sandfly bites is the primary means of prevention. Sandfly eradication programs have been helpful in decreasing the sandfly population, and insect repellant can be effective in preventing sandfly bites.

Basal cell cancer *see* **Skin cancer**

Basal cell carcinoma

Definition

A basal cell carcinoma is a **skin cancer** that originates from basal keratinocytes in the top layer of the skin, the epidermis. Sometimes these tumors are called "rodent ulcers."

Demographics

Basal cell carcinomas are most common from middle age until old age. They are more frequent in men than women. These cancers seem to be associated with exposure to ultraviolet light; they tend to develop on sun-exposed areas and are more common in people living near the equator. Those who have lighter skin are more susceptible; fair-haired blonds are more likely to develop tumors than people with darker complexions. In the United States, Caucasians have a 23% to 39% chance of developing a basal cell carcinoma over a lifetime.

Weakened immunity may also play a role. Those who have had an organ transplanted or who have contracted acquired immune deficiency syndrome (**AIDS**) are more likely to develop one of these cancers.

Basal cell carcinomas are particularly common among individuals with a rare genetic disease called nevoid basal cell carcinoma syndrome (Gorlin's syndrome). Individuals with this disease can be born with basal cell carcinomas or begin to develop them in childhood. Some have few or no cancers; others have more than 250. These tumors seldom grow much before **puberty**, but during and after adolescence they can spread rapidly. Other symptoms include small pits in the palms and soles, cysts in the jaw, and other abnormalities in the bones.

Description

Basal keratinocytes are unpigmented skin cells found deep in the epidermis, hair follicles, and sweat glands. When they become cancerous, these cells invade the dermis (the layer of skin just below the epidermis) and spread out into the normal skin. They become visible as a small growth or area of change in the skin's appearance. These tumors can appear anywhere on the body, but most become evident on the face and neck.

Most basal cell carcinomas are small tumors that can be cured with simple surgeries. They usually grow quite slowly. However, neglected or aggressive tumors can invade vast amounts of skin. These cancers can also spread along bones, cartilage, muscles, and, more rarely, nerves. Some tumors may eventually reach the eye or brain or become large enough to significantly disfigure the face. These serious consequences are more likely if the tumor lies close to bone and cartilage—for instance, at the corner of the eye. Very few basal cell carcinomas spread to more distant organs; the incidence of metastatic basal cell carcinoma is less than 0.1%. Most that do are very large, deep cancers that have been visible for years.

KEY TERMS

Albinism—A genetic disease characterized by the absence of the normal skin pigment, melanin.

Biopsy—A sample of tissue taken to look for abnormalities. Also, the technique used to take such samples.

Dermis—A layer of skin sandwiched between the epidermis and the fat under the skin. It contains the blood vessels, nerves, sweat glands, and hair follicles.

Epidermis—The thin layer of skin cells at the surface of the skin.

Fluorouracil—A cancer drug.

Hair follicles—The structures in the skin that make each hair.

Imiquimod—A drug, approved by the FDA to treat warts, that may destroy basal cell carcinomas by stimulating the immune system. Also known by its trade name Aldara.

Interferon alpha—A chemical made naturally by the immune system and also manufactured as a drug.

Local anesthetic—A liquid used to numb a small area of the skin.

Lymph node—A small structure located at various places in the body (part of the lymphatic system)

Causes and symptoms

Basal cell carcinomas are caused by genetic damage to a skin cell. Exposure to ultraviolet light and x rays, suppression of the immune system, and genetic factors seem to increase the risk that this will happen. Frequent or severe sunburns during childhood, frequent sunbathing or exposure through **tanning** beds, occupational exposure to sunlight due to outdoor employment (farming, construction, fishing), treatment of **acne** using x rays, or exposure to arsenic through drinking well water may all increase a person's risk of developing basal cell carcinoma.

Several types of basal cell carcinomas exist. Nodular basal cell carcinomas are the most common form. These tumors begin as a tiny red or clear bump on the skin. Over time, they develop into a growth with clear or white "pearly" raised edges and, often, a depressed area in the middle. A network of tiny blood vessels usually crisscrosses the surface, and the tumor may bleed repeatedly or crust over. Morpheaform (sclerosing, morpheic) basal cell carcinomas are more difficult to detect. These tumors are usually pale, firm, flat growths that can blend into the normal skin around them. Many look just like a scar. Superficial basal cell carcinomas are flat, red, scaly plaques that can look like **psoriasis** or **eczema**. Unlike other basal cell carcinomas, they are usually found on the arms, legs, and torso. Pigmented basal cell carcinomas are brown, black, or blue; they are usually of the nodular type and can look like a **melanoma**.

Some general characteristics of skin cancers include:

- irregular or ragged borders
- non-symmetrical shape
- a change in color
- a size greater than 0.2 inches (6 mm)

Diagnosis

Basal cell carcinomas are usually diagnosed with a **skin biopsy** taken in the doctor's office. This is generally a brief and simple procedure. Biopsy may or may not require numbing of the skin with injection of local anesthetic. A shave biopsy removes a tiny bit of superficial tissue; a punch biopsy removes a slightly larger, deeper sample. The skin biopsy must be sent to a trained pathologist to be analyzed. It may take up to a week for the biopsy results to come back. Sometimes the tumor is removed immediately after the biopsy, before the results are known.

Clinical staging, treatments, and prognosis

Basal cell carcinomas rarely spread into the lymph nodes and internal organs. For this reason, doctors tend not to stage them. If staging is needed, the TNM (tumor, lymph node, and metastases) system is usually used. For basal cell carcinomas, this can be simplified into the following five categories:

- Stage 0: The cancer is very small and has not yet spread from the epidermis to the dermis.
- Stage 1: The cancer is less than 2 cm (0.8 inches) in diameter. No cancer cells can be found in lymph nodes or other internal organs.
- Stage 2: The cancer is more than 2 cm (0.8 inches) in diameter. No cancer cells can be found in lymph nodes or other internal organs.
- Stage 3: Cancer cells have been found either in nearby lymph nodes or in the bone, muscle, or cartilage beneath the skin (or in both locations).

WWW.BOOKBAZ.IR

designed to filter the flow of lymph, a usually clear fluid that originates from stem cells.

Nonsteroidal anti-inflammatory drugs (NSAIDS)—A class of drugs that suppresses inflammation. Includes a wide variety of drugs, such as aspirin.

Oncologist—A doctor who specializes in the treatment of cancer.

Pathologist—A doctor who specializes in examining cells and other parts of the body for abnormalities.

Premalignant skin lesion—An abnormal change in the skin that has a good chance of turning into skin cancer but is not yet cancerous.

Selenium—A mineral needed in extremely small quantities by the body. Large amounts can be very toxic.

Squamous cell carcinoma—A type of skin cancer.

Sweat glands—Tiny glands scattered throughout the skin that produce sweat.

TNM system—A commonly used staging system that examines the main tumor (T), the lymph nodes (N), and metastases (M).

Xeroderma pigmentosum—A genetic disease characterized by the inability to repair damaged DNA. Individuals with this disease develop an excessive number of skin cancers.

- Stage 4: Cancer cells have been discovered in internal organs, most often the lungs or lymph nodes, that are distant from the skin. A stage four cancer can be any size.

Treatment

Treatment options for non-metastatic, non-staged tumors

For most non-metastatic, non-staged cancers, there may be several treatment options. The recommended treatment depends on the size and type of tumor, its location, and cosmetic considerations. The cure rates for most of the following techniques are approximately 85% to 95%, but vary with tumor size and other factors. Moh's micrographic surgery has a five-year cure rate of 96%. Success rates for recurrent tumors are approximately 50% with most techniques and 90% with Moh's surgery.

In conventional surgery, the doctor numbs the area with an injection of local anesthetic, then cuts out the tumor and a small margin of normal skin around it. The wound is closed with a few stitches. One advantage to conventional surgery is that the wound usually heals quickly. Another benefit is that the complete cancer can be sent to a pathologist for evaluation. If the skin around the tumor is not completely free of cancer cells, the tumor can be treated again immediately.

Moh's micrographic surgery is a variation of conventional surgery. In this procedure, the surgeon examines each piece of skin under the microscope as it is removed. If any cancer cells remain, another slice is taken from that area and checked. These steps are repeated until the edges of the wound are clear of tumor cells, then the wound is closed. The advantage to this technique is that all of the visible cancer cells are removed but as much normal skin as possible is spared. Moh's surgery is often used for larger or higher risk tumors and when cosmetic considerations are important. The main disadvantage is that it takes much longer than conventional surgery and requires a specially trained surgeon.

A laser is sometimes used as a cutting instrument instead of a scalpel. Laser light can also destroy some cancer cells directly. A disadvantage to **laser surgery** is that the **wounds** from some lasers heal more slowly than cuts from a scalpel. The advantage is that bleeding is minimal.

In electrodessication and curettage, the physician scoops out the cancer cells with a spoon-shaped instrument called a curette. After most of the tumor is gone, the remaining cancerous tissue is destroyed with heat from an electrical current. The wound is left open to heal like an abrasion. It leaks fluid, crusts over, and heals during the next two to six weeks. This is a safe and easy method for removing many basal cell carcinomas. One disadvantage is that there is no skin sample to confirm that the tumor is completely gone. The electrical current used during this surgery can interfere with some **pacemakers** and larger tumors may heal with a noticeable scar.

In cryosurgery, liquid nitrogen is used to freeze the tumor and destroy it. This treatment is another type of blind destruction; there is no skin sample to make sure the cancer cells have all been killed. Patients

report swelling and **pain** after cryosurgery, and a wound appears a few days later where the cells were destroyed. When the site heals, it has usually lost its normal pigment. There is a risk of nerve damage with this technique.

Radiation therapy is an uncommon treatment for basal cell carcinoma. One disadvantage is the inconvenience: multiple treatments, over a period of weeks, are necessary. Tumors that return after radiation also tend to grow more quickly than the original cancer. In addition, x rays may promote new skin cancers. Radiation therapy may be an option for patients who cannot undergo even minor surgery. It is also used occasionally as an adjunct to surgery. One advantage is that the cosmetic results can be very good.

Occasionally a lotion containing fluorouracil is applied to the tumor. This drug cannot penetrate very far and cancer cells in the deeper parts of the tumor may not be destroyed. The main advantage to this treatment is its simplicity.

Treatment options for metastatic cancers

Cancers that have spread to internal organs are treated with a combination of surgery, radiation, and **chemotherapy**.

Special concerns

Because many basal cell carcinomas are found on the face and neck, cosmetic concerns are a priority for many patients. If there is a risk of noticeable scarring or damage, a patient may wish to ask about alternative types of removal or inquire about the services of a plastic surgeon.

After treatment, it is important to return to the doctor periodically to check for regrowth or new skin cancers. Approximately 36% of all patients find a new basal cell or squamous cell carcinoma within the next five years. Having a basal cell carcinoma before the age of 60 may also increase the chance of developing other cancers in internal organs.

Prognosis

The prognosis for small, uncomplicated basal cell carcinomas is very good. The vast majority of these tumors can be successfully removed. However, cancers that were not completely destroyed may regrow. If the edges of the removed skin contain cancer cells, the chance that the tumor will return within the next five years is about 40%. Regrowth is more likely with cancers larger than 0.8 inches (2 cm), those on the face (particularly around the nose, eye, and ear), and higher-risk types such as morpheaform tumors. Tumors can redevelop in the scar from the surgery, on the edges of the surgery site, or deep in the skin. These cancers may not look like the original tumor. Patients should be particularly watchful for minor changes in the appearance of the scar or sores that appear nearby.

Cancers that metastasize spread most often to the lymph nodes and lungs. The prognosis for metastatic cancers is poor, even with treatment. Survival after spread of the cancer to internal organs is eight months on the average and seldom more than a year and a half.

Prevention

The risk factors for basal cell carcinoma include:

- ethnic background
- complexion
- geographic location
- increasing age
- exposure to x rays and ultraviolet light (both UVA and UVB)
- a history of premalignant skin lesions or skin cancer
- genetic disorders such as nevoid basal cell carcinoma syndrome, xeroderma pigmentosum, and albinism
- suppression of the immune system by AIDS or an organ transplant

Some important preventive steps include wearing protective clothing and hats in the sun, using a sunscreen, avoiding the sun between 10 a.m. and 4 p.m., and staying away from suntanning booths. Checking the skin for early signs of cancer also is critical.

Drugs related to **vitamin A** (including beta-carotene, retinol, and isotretinoin), **vitamin E**, **nonsteroidal anti-inflammatory drugs** (NSAIDS), and selenium have been suggested as possibly preventing basal cell carcinoma. A 2003 study reported that selenium is not effective in preventing basal cell carcinoma and may even increase risk of squamous cell carcinoma.

Battered child syndrome

Definition

Battered child syndrome refers to injuries sustained by a child as a result of physical **abuse**, usually inflicted by an adult caregiver. Alternative terms include: shaken baby; **shaken baby syndrome**; **child abuse**; and non-accidental **trauma** (NAT).

Description

Internal injuries, cuts, **burns**, **bruises**, and broken or fractured bones are all possible signs of battered child syndrome. Psychological damage to a child is also often the by-product of child abuse and can result in serious behavioral problems such as substance abuse or the physical abuse of others. According to the U.S. Department of Health and Human Services Administration for Children and Families, in 2008, 1,740 child fatalities resulted from child abuse. Of these, more than three-quarters of the children were under four years old, with the largest number of deaths occurring in infants under one year old. In addition, about 772,000 children were documented victims of nonfatal maltreatment, a term that includes neglect and psychological abuse, as well as physical and **sexual abuse**. About 80% of abused children were abused by a parent or a parent acting with another individual.

Causes and symptoms

Battered child syndrome (BCS) is found at every level of society, although the incidence may be higher in low-income households where adult caregivers experience greater financial **stress** and social difficulties, have less education and understanding of child development, and may have less access to social services. In addition, children of parents who are substance abusers are more likely to experience abuse than children living in households where there is no substance abuse. Many child abusers were also themselves abused as children.

The child batterer most often injures a child in the heat of anger. The incessant crying of an infant or child, refusal to follow directions, or the child creating a mess or breaking an object may trigger abuse. Symptoms may include a delayed visit to the emergency room with an injured child, an implausible explanation of the cause of a child's injuries, bruises that match the shape of a hand, fist or belt, cigarette burns, scald marks, bite marks, black eyes, unconsciousness, bruises around the neck, and a bulging fontanel in infants.

Diagnosis

Battered child syndrome is most often diagnosed by an emergency room physicians, pediatricians, teachers, or social workers. **Physical examination** detects bruises, burns, swelling, or **retinal hemorrhage**. X rays, MRI, CT, or other imaging techniques may confirm bone **fractures** or internal soft tissue injuries. The presence of injuries at different stages of healing (i.e., having occurred at different times) is nearly always indicative of BCS. Establishing the diagnosis is often hindered by the caregiver's intentional concealment of the true origin of the child's injuries, as a result of fear, shame, avoidance, or denial mechanisms.

Treatment

Medical treatment for battered child syndrome varies according to the type of injury incurred. Counseling and the implementation of an intervention plan for the child's parent(s) or guardian(s) is necessary. The child abuser may be incarcerated, and/or the abused child removed from the home to prevent further harm. Reporting child abuse to authorities is mandatory for doctors, teachers, and childcare workers in most states as a way to prevent continued abuse. Both physical and psychological therapy are often recommended as treatment for the abused child.

KEY TERMS

Fontanel—Soft spot on top of an infant's skull.

Retinal hemorrhage—Bleeding in the back of the eye.

Prognosis

The prognosis for battered child syndrome depends on the severity of injury, actions taken by the authorities to ensure the future safety of the injured child, and the willingness of parents or guardians to seek counseling for themselves as well as for the child.

Prevention

Recognizing the potential for child abuse in a situation, and the seeking or offering of intervention and counseling before battered child syndrome occurs is the best way to prevent it. Signs that a child may be at risk for physical abuse include parental alcohol or substance abuse, previous abuse of the child or the child's siblings, history of mental or psychological problems in parents, parents abused as children, absence of visible parental love or concern for the child, and the child's hygiene neglected.

Baylisascaris

Definition

Baylisascaris are a genus of parasitic roundworms. *Baylisascaris procyonis* is found in raccoons and *Baylisascaris columnaris* is found in skunks. Baylisascaris is a zoonotic disease. Although it happens infrequently, these roundworms can infect humans, with serious results.

Description

Baylisascaris is important to **public health** because it can cause serious, although infrequent, infections in humans. Wildlife officials emphasize campaigns to make the public aware of the disease and the need to seek early treatment. Avoiing human interactions with raccoons is emphasized, as controlling the raccoon population is not a realistic option.

Baylisascaris is found in the small intestine of raccoons and skunks. The threat to humans is more likely to come from raccoons because they often live in close proximity to humans. The worms measure 6–8 inches (15–20 cm) long and about .4 in. (1 cm) wide.

Eggs are excreted in the feces of infected animals. Young raccoons can become infected in the den by ingesting eggs excreted by the mother. Older raccoons can be infected by eating birds or small mammals such as mice, squirrels, and rabbits that are also infected with the roundworms. Humans most often become infected by unintentionally ingesting dirt that contains eggs excreted by an infected animal. Dogs exposed to raccoon feces can also become infected and should be dewormed under the care of a veterinarian.

Risk factors

Infected raccoons are found throughout the United States and Canada, with the heaviest concentrations of infected animals in the United States found in the Northeast, Midwest, Mid-Atlantic and West Coast. Children are at greater risk than adults because they are more likely to eat dirt and put dirty hands into their mouths. Hunters, trappers, taxidermists, and wildlife handlers are also at higher risk if they interact with raccoons.

Demographics

According to the United States Centers for Disease Control and Prevention (CDC), as of 2012, fewer than 25 cases of Baylisascaris infection had been reported. Additional cases may have been misdiagnosed and

WWW.BOOKBAZ.IR

gone unreported because the infection is rare. Cases that have been diagnosed have been severe.

Causes and symptoms

Baylisascaris is caused by infection with the roundworm *Baylisascaris procyonis* or extremely rarely *Baylisascaris columnaris*.

When humans ingest Baylisascaris eggs, the eggs hatch into larvae in the intestine. The larvae then migrate through the body and settle in the brain, spinal cord, eye, muscles, or other internal organs. Symptoms depend on there the larvae settle and how many eggs were ingested. Symptoms take a week or more after infection to develop.

Common symptoms can include:

- fatigue
- nausea
- hepatomegaly (larvae settle in liver)
- cough or chest pain (larvae settle in lungs)
- loss of muscle control(larvae in muscles)
- loss of coordination (larvae in brain or spinal cord)
- blindness (larvae in eye)
- mental changes (larvae in brain)
- coma (larvae in brain)

Of the cases reported to the CDC as of 2012, 16 had nervous system complications and 6 resulted in death.

Diagnosis

Baylisascaris is difficult to diagnose, both because of its rarity and because its symptoms depend on where the larvae settle. Larvae can sometimes be detected in cerebrospinal fluid, but are most easily detected when they enter the eye and cause lesions.

Treatment

No drug is completely effective against this roundworm. Albendazole works against a wide range of parasitic worms and is usually the drug of choice. Early treatment is essential and should begin after know exposure to raccoon feces or on finding eggs in the feces of an animal the individual had handled. If give early (within 1–3 days after exposure) the drug may prevent migration of the larvae.

Alternatives

There are no known alternative treatments to Baylisascaris infection.

Prognosis

So few cases of Baylisascaris infection have been reported that it is difficult to predict outcomes. Early treatment improves the odds of complete recovery. Late or no treatment leads to permanent complications and increases the risk of death.

Prevention

Humans can avoid becoming infected with Baylisascaris by avoiding raccoon feces and practicing good handwashing procedures. Children should wash their hands whenever they come in from playing outside and be discouraged from eating soil and putting outdoor objects in their mouths, especially if they live in areas where raccoons are present.

Raccoons should not be kept as pets, and rescuers/rehabilitators should take precautions to avoid feces by wearing gloves and practicing diligent personal hygiene.

Raccoons sometimes invade attics, sheds, or other spaces shared with humans. If clean-up of these areas is necessary and a professional cleaning service is not used, individuals should wear gloves, a respirator if the space is enclosed, or if not, a mask, and disposable clothing to avoid contamination with feces.

Bedbug infestation

Definition

Bedbug infestation is the contamination of bedding, clothing, and household furnishings with the insect *Cimex lectularius* or *C. hemipterus*, commonly known as bedbugs. The bedbug is sometimes also spelled as two words, bed bug, or hyphenated, bed-bug.

Description

Bedbugs are small (from 0.20 to 0.32 in. or from 5 to 8 mm), oval, reddish-brown insects that feed on blood of birds and mammals. They are primarily nocturnal, feeding at night. During the day, they hide in mattress seams, cracks in bed frames or other furniture, behind loose wallpaper, and in bedding and clothing. Females lay large numbers of eggs that hatch in four to five days. Adults can live for months without feeding.

Bedbugs are survivors. Many common insecticides will not harm them. They quickly crawl from room to room or apartment to apartment. The most effective extermination methods involve simultaneous application of special insecticides, removal of infected beds, and washing and drying at high temperatures all potentially infested bedding and clothing.

Magnified image of a bedbug, which can often be found clinging to mattresses. *(© Dennis Kunkel Microscopy, Inc./ Visuals Unlimited/Corbis.)*

Bedbug bites are painless, but the bites cause an allergic reaction in most people resulting in an itchy, red rash. Although bedbug bites are rarely medically dangerous, they can become infected through scratching.

Demographics

Before 1950, bedbugs were common worldwide. The development of the pesticide dichlorodiphenyltrichloroethane (DDT) eliminated bedbugs from most developed countries. However, after DDT use was banned because of its harmful effects on the environment, bedbugs made a comeback. Bedbug infestation is relatively common in developed countries and very common in underdeveloped countries. Bedbugs spread easily, often via international travelers, and are difficult to exterminate. Bedbugs are equal opportunity pests, showing no preference in the age, gender, or race of their victims.

In 2009, several members of the U.S. House of Representatives introduced bill H.R. 2248, informally called the *Don't Let the Bed Bugs Bite Act of 2009*. For the purpose of establishing "a grant program to assist States in inspecting hotel rooms for bed bugs, and for other purposes." Part of the bill described the findings of Congress on the frequency that bedbugs infect parts of the country. In addition, a study referred to in the bill found that of 700 hotel rooms studied between 2002 and 2006, 25% of them were "in need of bedbug treatment." The bill also stated that the bedbug populations in the United States had increased five-fold over the past several years. Even though the bill did not pass the House, it clarified the growing problem with bedbugs in the United States.

Causes and symptoms

The bite of a bedbug causes an allergic reaction in most people that can be difficult to differentiate from skin reactions caused by other bites or **allergies**. The rash caused by bedbugs is red and itchy, and typically darker in the center of the bite. Often, but not always, bites form lines or groups of three, sometimes called breakfast, lunch, and dinner. Although bedbugs will bite any exposed skin, bites are most often found on the face, neck, arms, and hands.

The time it takes a bedbug rash to appear varies, ranging from as long as 10 days to less than one minute. Generally, the more frequently a person is exposed to bedbugs, the shorter the time it takes for the rash to appear. In rare cases, some individuals can have an extreme, life-threatening allergic reaction to bedbug bites called **anaphylaxis** or anaphylactic **shock**.

WWW.BOOKBAZ.IR

Bedbugs can be infected with the **hepatitis B** virus and with the parasite that causes Chagas disease.

Besides the obvious signs of bedbugs, some psychological problems can also develop due to the stigma associated with them. Serious infestations of bedbugs, and their resulting visible symptoms, can cause **anxiety**, **insomnia**, and **stress**. A medical condition called refractory delusional parasitosis can sometimes result in which a person acquires an exaggerated obsession to rid themselves of bedbugs.

Diagnosis

Medical diagnosis is not always necessary; individuals can make the diagnosis based on their past experience with bedbugs and recent history of travel or examination of their bedding for signs of infestation. When a medical diagnosis is sought, it is made based on the appearance of the rash along with a detailed history of recent travel and hotel stays. The doctor may also inquire about any drugs, herbs, or supplements being taken to help eliminate other possible causes of the rash. There are no tests to diagnose bedbug bites.

Prevention

Prevention is difficult. Avoiding secondhand bed frames, mattresses, and beds is helpful. Birds and bats can carry bedbugs, so they should be eliminated from attics and eaves. Checking the seams of mattresses for dark specks of bedbug excrement in hotels is helpful but not foolproof. The Mayo Clinic provides the following suggestions for preventing bedbug infestations at home or away:

- Cover up. Because bedbugs do not usually burrow under clothing, bites by bedbugs can be generally avoided by wearing pajamas that cover as much skin as possible.
- Secondhand items. Before bringing used mattresses or upholstered furniture into the home, carefully inspect all such items.
- Hotel precautions. Check mattress seams for bedbug excrement; place luggage on tables or dressers, not on the floor.

Treatment

The treatment of bedbug infestations may be concentrated on the individual and on the infested environment.

Treatment of the individual

The symptoms and rash associated with bedbug bites go away on their own, usually within a week to ten days. An over-the-counter skin cream containing hydrocortisone may be applied to reduce **itching**. An over-the-counter antihistamine containing diphenhydramine (e.g., Benadryl) may also help reduce itching. Parents of affected infants and children and pregnant and **breastfeeding** women should consult an appropriate healthcare professional before using these medications.

Treatment of the infested environment

Ridding an infested environment of bedbugs is considerably more difficult than treatment of the individual. A professional exterminator experienced with bedbug elimination may be required. Because bedbugs can hide in small cracks in furniture, mattresses, and box springs, vacuuming will not remove all of them. Special mattress covers can be purchased to lock out bedbugs, but it may be more effective to purchase a new mattress and box springs. Bedbugs can live for nine to 12 months without feeding.

Bedbugs can be killed by heat. Bedding and clothing should be washed in hot water and dried at very hot temperatures. The temperature must reach at least 120°F (49°C). Items that cannot be washed can be put in sealed plastic bags and placed in a car with the windows rolled up in the summer when the temperature will reach 120°F (49°C) or more inside the car. Freezing is less effective. Items must be left at temperatures below 32°F (0°C) for several days to kill bedbugs.

Insecticides effective against bedbugs include pemethrin and diethyltoulamide. Pemethrin spray can be used on clothing. Diethyltoluamide in high concentrations can be toxic to infants and children. People should consult a physician before using it. A professional exterminator is the safest way to rid the environment of bedbugs.

Room foggers and sprays against mosquitoes and ticks are ineffective against bedbugs. Many treatments for the elimination or prevention of bedbugs are sold over the Internet. These vary considerably in cost and effectiveness, so it is important to research products before buying.

Prognosis

Almost everyone recovers from bedbug bites within two weeks. Complications may arise from scratching the bites so that they become infected. If

infection occurs, then an antibiotic may be prescribed. Very rarely do bedbug bites transmit hepatitis B or Chagas disease to humans. Since bedbugs do not stay on the skin, a way to kill bedbugs on the body is not necessary. For the most part, the medical community believes that bedbugs do not transmit diseases; however, as of 2013, comprehensive research was lacking in this area. As long as a disease has not been transmitted to a human, only the itching needs to be treated so eventually the rash will go away.

The more often people are exposed to bedbug bites, the more highly sensitized they are. As sensitivity increases, the time it takes to produce a reaction decreases. If there is a delay of several days before the rash appears, it can be difficult to tell exactly where the bedbug bites were acquired.

The resistance of bedbugs to pesticides increased significantly in the late twentieth century. There are also serious health problems associated with pesticides. For these reasons, multiple approaches may be necessary to rid an environment of bedbugs.

Precautions

Several precautions can be used to help minimize ever getting bedbugs. Mattress encasements for each mattress and box spring can be purchased. Such enclosures help to prevent bedbugs from gaining entrance to the bed. Bedding materials, such as sheets and pillowcases, should be washed and dried in the hottest setting possible. This will kill any bedbugs attached to such materials. Pillows should be periodically cleaned. Even when clean, pillows should be regularly placed in a dryer at the highest temperature setting to help eradicate bedbugs.

Risks

People often associate bedbugs with poor or dirty living conditions, but bedbugs can be found in clean environments. In the early 2000s, complaints about bedbugs in both budget and first-class hotels increased.

The risk of exposure to bedbugs increases with certain activities:

- international travel
- frequent overnight stays in hotels and motels
- living in refugee camps or homeless shelters
- living in apartment buildings (bedbugs are efficient crawlers and can move through cracks from apartment to apartment)
- living in military barracks or dormitories

KEY TERMS

Anaphylaxis—Also called anaphylactic shock; a severe allergic reaction characterized by airway constriction, tissue swelling, and lowered blood pressure.

Chagas disease—A parasitic disease that causes mild early swelling at the site of the infection then becomes asymptomatic for many years but later may cause serious heart and digestive system problems. Parasites causing this disease are most common in rural Central and South America.

Hepatitis B—A disease that causes inflammation of the liver and serious liver damage.

Bedsores

Definition

Bedsores are tender or inflamed patches that develop when skin or underlying tissue covering a weight-bearing part of the body is squeezed between bone and another body part or a bed, chair, splint, or other hard object. These injuries often occur to skin that covers bony areas of the body such as the ankles, buttocks, heels, or hips. Bedsores, also called decubitus **ulcers**, pressure ulcers, or pressure sores, can develop quickly and become difficult to treat, especially for certain individuals who are susceptible to them.

Description

According to the Agency for Healthcare Research and Quality (AHRQ), a part of the U.S. Department of Health and Human Services, each year (as of 2011), about 2.5 million people in the United States develop bedsores ranging from mild inflammation to deep **wounds** that involve muscle and bone. This usually painful condition generally starts with shiny red skin that quickly blisters and deteriorates into open sores and can harbor life-threatening infection. In fact, according to the AHRQ, about 60,000 people die as a direct consequence of bedsores each year.

Bedsores are not cancerous or contagious. They are most likely to occur in people who must use wheelchairs or who are confined to bed, such as quadriplegics or long-term hospital patients. Bedsores are most apt to develop on the following parts of the body:

- ankles
- back of the head (cranium)
- heels
- hips
- knees
- lower back
- back of the arms and legs
- shoulders and shoulder blades
- spine, including the sacrum, or the large, triangular bone located at its base and the upper and back parts of the pelvic cavity
- tailbone (coccyx) or buttocks

Bedsore. *(Custom Medical Stock Photo, Inc.)*

For people confined to wheelchairs, bedsores are frequently found on the tailbone and buttocks, shoulder blades and spine, and the backs of arms and legs. For bedridden people, bedsores often arise on the sides and back of the head; shoulders or shoulder blades; rim of the ears; the hips, lower back, or tailbone; and the ankles, heels, or skin behind the knees.

Demographics

People who are more likely to develop bed sores are those with medical conditions that restrict their ability to change positions, such as those in wheelchairs or confined to beds for long periods. Those over the age of 60 years are more likely than are younger people to develop bedsores because older people have thinner, less elastic, drier, and more fragile skin. Risk in all people of any age is increased by following factors:

- generally poor health and weakness
- injuries that require bed rest or wheelchair use, such as post-surgical recovery
- prolonged bed rest, especially in unsanitary conditions or with wet or wrinkled sheets
- coma
- diseases that reduce blood flow (which leads to poor circulation) to the skin and soft tissues, such as atherosclerosis (hardening of arteries)
- diseases and conditions that reduce the sensation or feeling in the skin, such as neuropathy and paralysis
- conditions that make the skin more susceptible to infection, such as diabetes
- heart problems
- microclimate (skin wetness caused by sweating, excessive skin dryness, or incontinence, the inability to control bladder or bowel movements)
- malnutrition, especially diets lacking sufficient protein
- obesity
- weight loss, especially during extended illnesses or injuries

- immobility, such as people who are unable to move or recognize internal cues to shift position
- spinal cord injuries
- anemia (lack of red blood cells)
- diuse atrophy (muscle loss or weakness from lack of use)
- smoking of tobacco products (which impairs blood circulation and reduces the amount of oxygen in the blood)
- decreased mental awareness (which causes less involvement in a person's awareness of bedsores)
- muscle spasms (which causes increased motion of the muscles against stationary objects)

Causes and symptoms

Bedsores are generally caused by three tissue forces: sustained pressure, shearing, and microclimate. Sustained press most often develops when constant pressure (compression) pinches tiny blood vessels that deliver oxygen and nutrients to the skin. When skin is deprived of oxygen and nutrients for as little as an hour, areas of soft tissue can die (from the partial or complete obstruction of blood flow) and bedsores can form.

Shearing is a force created when the skin remains stationary as muscles and bones slide down from the force of gravity or when skin and muscles/bones move in opposite directions. For example, when a hospital bed is elevated at the head, the person's body may slide down the length of the bed, causing shearing motion of the moving skin with the stationary bed. In addition, slight rubbing or friction (both minor forms of shearing) against the skin can cause small pressure ulcers. They can also develop when a patient stretches or bends blood vessels by slipping into a different position in a bed or chair.

Microclimate is the condition of moisture and temperature against the skin that is in contact with a surface, such as a bed or wheelchair. Moisture on the skin (such as from perspiration or sweating) can cause the skin to lose its dry outer surface. Thus, it can allow the skin to lose its ability to tolerate pressures and shearing. Other conditions besides perspiration and sweating can cause this problem, including incontinence.

The primary symptoms of bedsores are (in order of severity, least to worst):

- redness of skin
- redness, swelling, and possible peeling of outer layer of skin
- dead skin, draining wound, and exposed layer of fat
- tissue death through skin and fat to muscle
- inner fat and muscle death
- destruction of bone, bone infection, fracture, and blood infection

Diagnosis

According to the Mayo Clinic, bedsores usually follow four primary stages that can be diagnosed by medical professionals:

- Stage I: the affected area appears as a pressure sore; the skin is intact but appears reddish in people with lighter skin color but may not appear noticeable at all in people with darker skin color; the site may be soft, firm, painful, and either warmer or cooler than unaffected skin
- Stage II: the area appears as an ulcer (an open wound); the epidermis (outer layer of the skin) and parts of the dermis (the underlying layer) appear damaged or missing; the affected area looks pinkish-red in color and shallow in contour
- Stage III: the affected area appears as a deep wound; due to the loss of skin, fat is exposed; the area has a crater-like contour; the bottom of the crater may contain dead yellowish tissue; the area may now extend past the original pressure sore
- Stage IV: the area shows definite loss of tissue; bone, tendons, or muscles may be exposed; the crater appears with dark, crusty dead tissue; the affected area extends into several layers of skin

Doctors can evaluate the size and depth of ulcers; check for bleeding in the wound, along with fluids or debris within the wound; determine if any odors are emanating from an infection or dead tissue; and assess wounds for signs of damaged tissue or infection.

Blood tests may also be recommended by the medical professional in order to assess overall health and nutritional status. Tissue cultures can be taken to determine any type of infection.

Bedsores can be predicted by doctors using the Braden Scale for Predicting Pressure Ulcer Risk. The Braden Scale, which was developed by Barbara Braden and Nancy Bergstrom in 1987, contains six areas that can be measured:

- cognitive/sensory perception (the ability to detect and respond to pain, discomfort, and other signals related to pressure on the body)
- mobility/immobility (the capability to adjust body position independently)
- activity/inactivity (the level of physical activity present in a patient, which determines the amount of atrophy within muscles)

WWW.BOOKBAZ.IR

- moisture (the amount of risk present on the skin from continuous moisture, which can compromise its integrity)
- nutrition (the amount of nutrition being taken in on a regular daily basis)
- shear/friction (the amount of assistance needed by a person to move about, especially with regards to the amount of sliding necessary to move between beds, chairs, and other structures)

Once measured, medical professionals can assess a patient's risk from developing bedsores.

Treatment

Prompt medical attention can prevent surface pressure sores from deepening into more serious infections. For mild bedsores, treatment involves relieving pressure, keeping the wound clean and moist, and keeping the area around the ulcer clean and dry. **Antiseptics**, harsh soaps, and other skin cleansers can damage new tissue, so a saline solution is used to cleanse the wound whenever a fresh nonstick dressing is applied.

Stage I and stage II bedsores generally heal within several weeks to a few months with proper and prompt care. Stage III and stage IV bedsores, however, are more difficult to treat and tend to require lengthier treatment periods.

The patient's doctor may prescribe infection-fighting **antibiotics**, special dressings or drying agents, or lotions or ointments to be applied to the wound in a thin film three or four times a day. Warm whirlpool treatments are sometimes recommended for sores on the arm, hand, foot, or leg.

The doctor often will prescribe a healthy diet for the patient, including one high in protein and rich in **vitamins** and **minerals**. Dietary supplements may also be prescribed such as vitamin C and zinc. Adequate hydration is also very important in the recovery of people with bedsores. The medical professional handling such cases will advise patients on the proper amount of fluids to drink on a daily basis. Doctors will also advise such patients to quit **smoking** if they are using tobacco products.

In a procedure called debriding, a scalpel may be used to remove dead tissue or other debris from the wound. Deep, ulcerated sores that do not respond to other therapy may require skin grafts or **plastic surgery**.

A doctor should be notified whenever a person is the following condition:

- will be bedridden or immobilized for an extended time
- is very weak or unable to move
- develops bedsores

Immediate medical attention is required whenever the following occur:

- Skin turns black or becomes inflamed, tender, swollen, or warm to the touch.
- The patient develops a fever during treatment.
- The sore contains pus or has a foul-smelling discharge.

With proper treatment, bedsores should begin to heal two to four weeks after treatment begins. However, the healing of bedsores may be slowed due to advanced age, medical conditions (such as arteriosclerosis, diabetes, or infection), smoking of tobacco products (such as cigarettes), or certain medications (such as anti-inflammatory drugs). The healing process may also be slowed in people who are critically ill, who are in wheelchairs (especially with regards to spinal cord injuries), and who are very frail.

Alternatives

Zinc and vitamins A, C, E, and B complex help skin repair injuries and stay healthy, but large doses of vitamins or minerals should never be used without a doctor's approval.

A poultice made of equal parts of powdered slippery elm (*Ulmus fulva*), marshmallow (*Althaea officinalis*, also called marsh mallow and common marshmallow), and **echinacea** (*Echinacea* spp.) blended with a small amount of hot water can relieve minor inflammation. An infection-fighting rinse can be made by diluting two drops of essential tea tree oil (*Melaleuca* spp.) in eight ounces of water. An herbal tea made from the calendula (*Calendula officinalis*) can act as an antiseptic and wound healing agent. Calendula cream can also be used.

Contrasting hot and cold local applications can increase circulation to the area and help flush out waste products, speeding the healing process. The temperatures should be extreme (very hot and ice cold), yet tolerable to the skin. Hot compresses should be applied for three minutes, followed by 30 seconds of cold compress application, repeating the cycle three times. The cycle should always end with the cold compress.

Prognosis

Bedsores can usually be cured, but about 60,000 deaths a year are attributed to complications caused by bedsores. In addition, according to the AHRQ, the treatment of bedsores and the associated expenses cost the U.S. economy from $9.1 billion to $11.6 billion

each year. Bedsores can be slow to heal. Without proper treatment, they can lead to the following:

- gangrene (tissue death)
- cellutitis (acute infection of the connective tissue within the skin)
- osteomyelitis (infection of the bone or joint beneath the bedsore)
- sepsis (tissue-destroying bacterial infection)
- other localized or systemic infections that slow the healing process, increase the cost of treatment, lengthen hospital or nursing home stays, or cause death

Prevention

It is usually possible to prevent bedsores from developing or worsening. The patient should be inspected regularly; should bathe or shower every day, using warm water and mild soap; and should avoid cold or dry air. A bedridden patient should be repositioned at least once every two hours while awake. Beds raised at the head should be elevated at an angle of no more than 30% to prevent shearing. Special mattresses and support surfaces can be used to relieve pressure. These materials include foam mattress pads, air-filled or water-filled mattresses, and special cushions.

Individuals who use wheelchairs should shift their weight every 10 or 15 minutes or be helped to reposition themselves at least once an hour. Specialized wheelchairs are available that help to alleviate pressure on the body. These so-called pressure-release wheelchairs tilt to redistribute pressure and provide some support when repositioning the user.

In all cases, it is important to lift, rather than drag, a person being repositioned. Bony parts of the body should not be massaged. Even slight friction can remove the top layer of skin and damage blood vessels beneath it.

If the patient is bedridden, sensitive body parts can be protected by the following:

- sheepskin pads
- special cushions placed on top of a mattress
- a water-filled mattress
- a variable-pressure mattress whose sections can be individually inflated or deflated to redistribute pressure

Pillows or foam wedges can prevent a bedridden patient's ankles from irritating each other, and pillows placed under the legs from mid-calf to ankle can raise the heels off the bed. Raising the head of the bed slightly and briefly can provide relief, but raising the head of the bed more than 30% can cause the patient to slide, thereby causing damage to skin and tiny blood vessels.

Individuals who use a wheelchair should be encouraged to sit up as straight as possible. Pillows behind the head and between the legs can help prevent bedsores, as can a special cushion placed on the chair seat. Donut-shaped cushions should not be used because they restrict blood flow and cause tissues to swell.

If any signs of infection appear (such as **fever**) or if a foul odor is present, then a doctor should be summoned immediately. In addition, any redness on the skin should be immediately evaluated to determine if a bedsore is beginning to appear.

KEY TERMS

Cellutitis—Acute infection of the connective tissue within the skin.

Friction—The resistance to motion such as that caused by a stationary surface being subjected to a moving surface.

Osteomyelitis—Infection of the bone or joint beneath the bedsore.

Sepsis—Tissue-destroying bacterial infection.

Shear—Motion that occurs when two surfaces move in opposite directions.

Bedwetting

Definition

Bedwetting, or nocturnal enuresis, is a condition of passing urine in bed during sleep after the age at which bladder control normally occurs. It is sometimes called **urinary incontinence**. It is a chronic condition that often resolves by itself before the teenage years. Bedwetting can be classified as either primary nocturnal enuresis (PNE), which means that the child has not yet had a prolonged period of staying dry at night; and secondary nocturnal enuresis (SNE), which occurs after a child has achieved nighttime dryness.

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM), classifies enuresis under the heading of disorders usually first classified in infancy, childhood, or adolescence, and defines it as "repeated voiding of urine during the day or at night into bed or clothes." The voiding of urine must occur at least twice per week for at least three months and not be caused by a medical condition. Even if the bedwetting does not meet the criterion of frequency, the manual allows the condition to be diagnosed if it causes the child significant emotional distress or impairs his or her social or academic functioning.

Demographics

Bedwetting is the single most common urologic complaint in children but is a developmental issue in most children rather than a psychological or medical disorder. Only 5–10% of cases of bedwetting are caused by medical conditions. The number of children with nocturnal enuresis decreases sharply after five years of age. According to the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), about 10% of five-year-olds, 5% of 10-year-olds, and 1% of 18-year-olds experience episodes of bedwetting. Bedwetting at all ages is twice as common in boys as in girls; males make up 60% of bedwetters overall and make up more than 90% of those who wet the bed every night. Various studies place adult bedwetting rates somewhere between 0.5% and 2.3%.

Bedwetting is known to run in families. A family history of bedwetting is found in 50% of children with secondary nocturnal enuresis. One study reported bedwetting in 43% of children whose fathers had a childhood history of bedwetting; 44% of children of enuretic mothers; and 77% of children whose father and mother had histories of bedwetting.

Bedwetting has recently been linked to specific loci on four different chromosomes. A locus on chromosome 13 was identified in 1995 as associated with bedwetting. Since then, other genetic loci have been identified on chromosomes 8, 12, and 16. It should be noted that the genes in these loci do not govern bedwetting by itself; rather, they control such factors associated with bedwetting as the ability to wake up when the bladder feels full or the capacity of the bladder to hold urine.

Description

One of the major tasks of toddlerhood is to learn how to achieve conscious control over the timing of urination. Most children do not become fully toilet trained until they are about two to four years old. Before then, the parts of the nervous system in charge of bladder control are not fully developed and functional. In general, boys take longer to learn to control their bladders than girls; most girls are dry at night by age six, but most boys do not achieve nighttime dryness until age seven. In addition, daytime bladder control is easier for a child than overnight bladder control. As of 2010, researchers did not yet fully understand why it is easier for young children to stay dry during the day than during sleep.

Risk factors

There were only three known risk factors for bedwetting as of 2010:

- family history of bedwetting
- gender—boys are more likely to have problems with bedwetting than girls

- Attention deficit hyperactivity disorder (ADHD)—bedwetting is more common in children diagnosed with ADHD

Race or ethnicity do not appear to be risk factors for bedwetting.

Causes and symptoms

Bedwetting is in most cases due to the normal immaturity of the nervous system and the urinary system. For instance, up to age six, bedwetting is often due to nothing more than the bladder having a small capacity. In addition, the muscles that control the opening and closing of the urethra may not be sufficiently developed. Often it takes a while for a child to learn recognition of bladder fullness, waking up, and going to the toilet. Sometimes chronic **constipation** causes bedwetting because the fullness of the child's large intestine reduces bladder capacity. Still another factor may be insufficient production of antidiuretic hormone (ADH), a hormone stored in the pituitary gland and released at night to slow down urine production. In most cases, urinary capacity and control increase over time, and the bedwetting problem will eventually be outgrown.

One major cause of bedwetting is lack of sleep. If a child is not sleeping enough hours, then there will be less of the light, rapid eye movement (REM) sleep, and more periods of heavy, deep sleep. During the periods of deep sleep some children have difficulty becoming aware of the urge to urinate and awakening to go to the toilet.

Bedwetting may be a sign of allergic reactions, which end up irritating sphincter muscles around the urethra. This contributes to a loss of bladder control during sleep. Heavy **snoring**, mouth breathing, and night sweats may all be indications of the presence of **allergies**.

In some cases, bedwetting is an early symptom of diabetes. Other signs and symptoms of this metabolic disease may include passing large amounts of urine all at once, increased thirst, unusual tiredness, and weight loss in spite of a good appetite.

Bedwetting can sometimes be due to emotional and psychological **stress**, including such major life changes as moving, starting school, the birth of a sibling, or the parents' divorce. This stress usually leads to the type of bedwetting called secondary nocturnal enuresis (SNE), in which a previous level of accomplishment with bladder control is lost. In other words, a child who has been dry at night will suddenly start wetting the bed again. This may indicate an underlying problem such as constipation, diabetes, physical defects in the urinary tract, sacral nerve disorders, a pelvic growth, urinary stasis, infection, **kidney stones**, or kidney damage. Secondary enuresis also frequently occurs in children who are being physically or sexually abused. A pediatrician should be consulted if the condition persists.

About 5% of cases of bedwetting are caused by a serious underlying medical problem. If the following symptoms are present, a pediatrician or a pediatric urologist should be consulted:

- straining during urination
- a burning feeling or other discomfort during urination
- constant or recurrent dribbling of urine
- cloudy or pink urine
- bloodstains or other discharge on underpants or nightclothes
- an unpleasant urine odor
- onset of abdominal pain, backache, or fever
- constant thirst, especially at night
- sudden loss of bladder control previously mastered
- a child over the age of two who still shows no signs of being ready to learn bladder control

Diagnosis

Examination

When bedwetting in a child is resistant to home treatments or when more serious symptoms are present, a visit should be made to a healthcare provider. This is especially warranted if the child is older than six. A thorough history and physical exam should be taken along with a urine sample. Analysis and culture tests can be done on the urine to determine if an infection is present.

Tests

Further evaluations may be made using **ultrasound**, an x ray of the kidney, or a consultation with a urologist. If the bedwetting appears to be connected with issues of stress or family problems, a mental health consultation may be recommended.

Bedwetting in adults is rare and should be promptly evaluated, as it is often a sign of a serious medical condition or disorder. Causes may include **bladder cancer**, obstructive **sleep apnea**, diabetes, disorders of the central nervous system, urinary tract enlargement, or stones in the urinary tract. Bedwetting in an adult male may be a symptom of prostate enlargement or **prostate cancer**. It is rare for **anxiety disorders** or other psychiatric disturbances to cause

WWW.BOOKBAZ.IR

KEY TERMS

Antidiuretic hormone (ADH)—A substance stored in the pituitary gland and released at night to diminish the formation of urine. It is also known as vasopressin.

Behavior modification—Therapy aimed at changing behavior by substituting problem behaviors with more useful activities.

Continence—The ability to control one's bladder and bowel functions.

Culture test—A laboratory test to grow samples of an infecting organism from discharge or samples of affected tissue.

Diuretic—A substance that stimulates the formation and excretion of urine.

Incontinence—Loss of bowel or bladder control.

Nocturnal enuresis—The medical term for bedwetting.

Rapid eye movement sleep (REM)—A stage of sleep during which dreams occur. This stage usually alternates with a heavier, more restful stage of sleep.

Sitz bath—A hydrotherapy treatment for soaking the pelvic or genital areas.

Urethra—The tube that drains urine from the bladder.

Urologist—A physician who specializes in treating problems of the urinary tract.

bedwetting in adults, but emotional stress has been known to cause occasional SNE in a small number of adults.

Treatment

Traditional

One option for treatment of bedwetting in children is simple watchful waiting. If the child does not seem to be emotionally upset by bedwetting episodes and there is no other major stress in the family, a reassuring talk with the pediatrician may be all that is needed. As children grow, their bladder capacity increases, the natural body signals to get up and urinate become more efficient, the production of ADH increases, and the child learns to respond to the body's signal to wake up and go to the bathroom.

Another option is mechanical bedwetting alarms. These are devices that consist of a moisture-sensitive pad worn inside the child's pajamas, a wire connected to a battery-operated control mechanism, and an alarm that sounds when the pad detects wetness. Ideally, the child will be awakened by the alarm in time to get to the bathroom before all of the urine has been voided. If the child is a very heavy sleeper, a parent or older sibling may need to sleep in the child's bedroom in order to awaken him or her when the alarm sounds. Some researchers have found that alarms are more effective with older children than with younger ones.

Behavior modification therapy may also be tried. A widely used program for bedwetters involves reminding the child to urinate before going to bed, recording wet and dry nights, changing wet clothing and bedding, and discussing progress. Positive reinforcements, such as gold stars on a chart and other rewards, are given for nights that the child does not urinate in bed. The International Children's Continence Society recommends a behavioral modification approach to bedwetting as well as age-appropriate explanations for children about other types of treatment for bedwetting.

Drugs

Medications may be useful in treating some cases of bedwetting, although doctors do not usually prescribe them for children younger than seven. The three drugs used most often are desmopressin (DDAVP), oxybutynin (Ditropan), and imipramine (Tofranil). Desmopressin, given as a pill or nasal spray, works by raising the levels of ADH in the body. Oxybutynin is a drug that works to relax the muscles in the bladder, preventing premature contractions. Imipramine is a tricyclic antidepressant that works on both the brain and the urinary bladder.

Medications are effective in about 70% of children with bedwetting problems. However, it is not unusual for children to relapse once the drugs are discontinued. In addition, all three drugs have side effects: desmopressin may cause seizures; oxybutynin may cause **dry mouth** and flushing; and imipramine can cause mood changes. Because an overdose of imipramine is potentially fatal in children, the antidepressant is usually prescribed only when other treatments fail.

Alternatives

HANDS-ON THERAPIES. **Acupressure**, **reflexology**, and **shiatsu** can be used to relax the child, counteract stress, and improve the actions of the nervous system. **Hypnotherapy** can also be helpful in improving bedwetting. Among other things, the child will be given

positive goal affirmations to say before going to bed. This should help make the urge to urinate during the night more conscious, and encourage the child to awaken and go to the toilet.

HOMEOPATHY. The best way to use homeopathy is to see a homeopath for individual prescribing. *Equisetum* 6c may be useful, especially if there are dreams or nightmares connected with the bedwetting. For bedwetting in very excitable, outgoing children, which occurs soon after falling asleep, *Causticum* 6c may be recommended. The remedies should be given once per day at bedtime for up to two weeks. A practitioner should be consulted for more specific remedies.

HERBAL MEDICINE. A strong tea can also be made using equal parts of horsetail, *Equisetum arvense;* St. John's wort; cornsilk, *Zea mays;* and lemon balm, *Melissa offinalis*. Two to three handfuls of the mixture should be placed in a quart or liter jar and then covered with boiling water. The tea should be allowed to steep overnight. The child should be given half a cup of the tea three times per day, with the last dose being given at least two hours before bedtime.

Nettles, *Urtica dioica,* can be made into a pleasant tea and consumed throughout the day as a tonic for the kidneys. The tea can be mixed with equal parts of fruit juice as a pleasant drink for the child.

AROMATHERAPY. Aromatherapy uses the essential oil of cypress, *Cupressus sempervirens* to treat chronic bedwetting. Several drops of cypress oil should be put in olive oil for massage. The oil should be rubbed onto the child's stomach right before bedtime.

Home remedies

Sitting in a cool **sitz bath** (with only the child's pelvic area immersed) for about five minutes daily can tone up the urethral sphincter. The sitz bath can be set up by using a bathtub filled with 2–3 in (4.5–6.6 cm) of water; having the child sit in a large basin of water; or purchasing a sitz basin (available from drugstores and medical supply stores).

Prognosis

Most children outgrow bedwetting at some point. Underlying disease conditions may have to be assessed and treated. The prognosis of bedwetting in adults depends on the underlying cause.

Prevention

Episodes of bedwetting cannot always be prevented, but the following measures are recommended to reduce their frequency:

- Limit the child's fluid intake in the evening.
- Avoid foods or drinks containing caffeine, which is a diuretic. Caffeine is contained not only in tea and coffee, but also in energy drinks, cola, hot chocolate, and foods containing chocolate.
- Encourage the child to urinate regularly throughout the day as well as just before bedtime. A common suggestion is to ask the child to urinate every two hours during the day.
- Make sure that constipation is treated if the child has problems with it.

Behcet's syndrome

Definition

A group of symptoms that affect a variety of body systems, including musculoskeletal, gastrointestinal, and the central nervous system. These symptoms include ulceration of the mouth or the genital area, **skin lesions**, and inflammation of the uvea (an area around the pupil of the eye).

Description

Behcet's syndrome is a chronic disease that involves multiple body systems. The disease is named for a Turkish dermatologist, Hulusi Behcet, who first reported a patient with recurrent mouth and genital **ulcers** along with **uveitis** in 1937. The disease occurs worldwide, but is most prevalent in Japan, the Middle East, and in the Mediterranean region. There is a wider prevalence among males than females in a ratio of two to one.

Causes and symptoms

The cause of Behcet's syndrome is unknown. Symptoms include recurring ulcers in the mouth or the genital area, skin lesions, arthritis that affects mainly the knees and ankles, **pain** and irritation in the eyes, and **fever**. The mouth and genital ulcers tend to occur in multiples and can be quite painful. In the mouth, these ulcers are generally found on the tongue, gums, and the inside of the lips or jaws. In the genital area, the ulcers usually occur on the penis and scrotum in males and on the vulva of women. The eye inflammation can lead to blindness.

Diagnosis

Because Behcet's syndrome is a multisystem disease, it is difficult to diagnose. International criteria have been proposed to assist in classifying this disease. There is no one diagnostic feature of this disease, so diagnosis depends on grouping together enough symptoms in order to identify the disease. Symptoms of Behcet's syndrome also occur in other diseases, so it is often necessary to rule out the other diseases before a definitive diagnosis can be reached.

Treatment

Some of the current drugs used to treat Behcet's syndrome include **corticosteroids**, cyclosporine, azathioprine, chlorambucil, interferon alpha, thalidomide, levamisole, and pulse cyclophosphamide.

Prognosis

The prognosis for Behcet's syndrome is generally poor. There has been a documented case of Behcet's lasting for 17 years. Although the disease is considered painful but not fatal, when the central nervous system is involved there is usually severe disability and death often occurs. The condition is usually chronic,

KEY TERMS

Remission—When active symptoms of a chronic disease are absent.

Uveitis—Inflammation of the area of the eye around the pupil.

although there can be remissions during the course of the disease. There is no predictable method to determine which patients will progress into the more serious symptoms, and which might move into remission.

Prevention

There is no known prevention for Behcet's syndrome.

Bejel

Definition

Bejel, also known as endemic **syphilis**, is a chronic but curable disease, seen mostly in children in arid regions. Unlike the better-known venereal syphilis, endemic syphilis is not a sexually transmitted disease.

Description

Bejel has many other names depending on the locality: Siti, dichuchwa, njovera, belesh, and skerljevo are some of the names. It is most commonly found in the Middle East (Syria, Saudi Arabia, Iraq), Africa, central Asia, and Australia. Bejel is related to **yaws** and **pinta**, but has different symptoms.

Causes and symptoms

Treponema pallidum, the bacteria that causes bejel, is very closely related to the one that causes the sexually transmitted form of syphilis, but transmission is very different. In bejel, transmission is by direct contact, with broken skin or contaminated hands, or indirectly by sharing drinking vessels and eating utensils. *T. pallidum* is passed on mostly between children living in poverty in very unsanitary environments and with poor hygiene.

The skin, bones, and mucous membranes are affected by bejel. Patches and ulcerated sores are common in the mouth, throat, and nasal passages. Gummy lesions may form, even breaking through the palate. Other findings may include a region of swollen lymph nodes and deep bone **pain** in the legs. Eventually, bones may become deformed.

Diagnosis

T. pallidum can be detected by microscopic study of samples taken from the sores or lymph fluid. However, since antibody tests do not distinguish between the types of syphilis, specific diagnosis of the type of syphilis depends on the patient's history, symptoms, and environment.

Treatment

Large doses of benzathine penicillin G given by injection into the muscle can cure this disease in any stage, although it may take longer and require additional doses in later stages. If penicillin cannot be given, the alternative is tetracycline. Since tetracycline can permanently discolor new teeth still forming, it is usually not prescribed for children unless no viable alternative is available.

Prognosis

Bejel is completely curable with antibiotic treatment.

Prevention

The World Health Organization (WHO) has worked with many countries to prevent this and

WWW.BOOKBAZ.IR

KEY TERMS

Endemic disease—An infectious disease that occurs frequently in a specific geographical locale. The disease often occurs in cycles. Influenza is an example of an endemic disease.

Lymph—The clear, colorless fluid found in lymph vessels and nodes. The lymph nodes contain organisms that destroy bacteria and other disease causing organisms (also called pathogens).

Syphilis—A disease that occurs in two forms. One is a sexually transmitted disease caused by a bacteria. The second form is not sexually transmitted, but passed on by direct contact with the patient or through use of shared food dishes and utensils.

other diseases, and the number of cases has been reduced somewhat. Widespread use of penicillin has been responsible for reducing the number of existing cases, but the only way to eliminate bejel is by improving living and sanitation conditions.

Jill S. Lasker

Bell's palsy

Definition

Bell's palsy describes the acute onset of an unexplained weakness or paralysis of the muscles on one side of the face. Afflicted individuals may be unable to close the eye on the affected side of the face, and may also experience tearing, drooling, and hypersensitive hearing on the same side. The onset can be quite sudden, sometimes occurring overnight. The weakness and paralysis resolve completely in the majority of cases. Although Bell's palsy cannot be considered a serious condition from a health standpoint, it can cause extreme stress, embarrassment, and inconvenience for those affected.

Description

Bell's palsy has been described as a diagnosis of exclusion because several other disorders exhibit similar symptoms. Facial palsies have been linked to conditions such as Lyme disease ear infection, meningitis, syphilis, German measles (rubella), mumps, chicken pox (varicella), and infection with Epstein-Barr virus (e.g., infectious mononucleosis). True Bell's palsy is an idiopathic facial palsy, meaning the root cause cannot be identified. Although Bell's palsy is not life-threatening, it can present symptoms similar to serious conditions such as stroke, ruptured aneurysm, or tumors.

Demographics

The annual incidence of Bell's palsy in the United states is about 23 cases per 100,000 population. Worldwide, incidence runs from about 15–30 cases per 100,000 population. An individual can be affected at any age, the peak incidence is in but young to middle-aged adults. It is unusual to see Bell's palsy in people less than 10 years old. Bell's palsy can affect either side of the face. Gender does not seem to factor into risk, though pregnant women, especially in the third trimester, and individuals with diabetes, influenza, a cold, or an upper respiratory infection seem to be at a greater risk. Cases are lowest during the summer.

In the large majority of cases (80–85%), the facial weakness or paralysis is temporary. However, individuals who experience complete paralysis seem to have a poorer recovery rate, with only 60% returning to normal. Approximately 4–6% of all Bell's palsy cases result in permanent facial deformity, and another 10–15% or individuals experience permanent problems with spasms, twitching, or contracted muscles. Between 2% and 7.3% of individuals who have had Bell's palsy experience a recurrence. On average, the first recurrence happens 9.8 years after the first episode; the second, 6.7 years later. One recurrence is very infrequent, and a second is extremely rare.

Causes and symptoms

The symptoms of Bell's palsy arise from an inflammation of the seventh cranial nerve, called the facial nerve. Each side of the face has a facial nerve that controls the muscles on that side of the face. Inflammation leads to the interference with conduction of nerve signals, and that in turn results in the loss of muscle control and tone.

Why the facial nerve becomes inflamed in Bell's palsy is a matter of considerable debate. Some evidence implicates the herpes simplex virus (HSV), which is responsible for cold sores and fever blisters. HSV infection has been suggested in up to 70% of Bell's palsy cases. Most people harbor this virus, although they may not exhibit symptoms. Symptoms are graded from 1–6 with 1 being normal facial functioning and 6 being complete paralysis.

A number of other conditions have also been associated with the development of Bell's palsy, including facial or head injuries, headache repeated middle ear infections, high blood pressure, diabetes, sarcoidosis, tumors, influenza, and other viral infections, as well as Lyme disease.

The major symptom of Bell's palsy is one-sided facial weakness or paralysis. Muscle control is either inadequate or completely missing. Patients frequently have difficulty shutting the affected eye and may not be able to close it at all.

Other symptoms can include pain in the jaw or behind the ear on the affected side, ringing in the ear, headache, decreased sense of taste, hypersensitivity to sound on the affected side, difficulty with speech, dizziness, and problems eating and drinking.

Diagnosis

Although Bell's palsy is not life threatening, it has similar symptoms to serious conditions such as stroke. The fact that Bell's palsy is a diagnosis of exclusion becomes apparent in the course of the medical examination—it is imperative to rule out other disorders. Disorders that need to be excluded include demyelinating disease (e.g., multiple sclerosis), stroke, tumors, bacterial or viral infection, and bone fracture. Therefore, emergency medical attention is a wise and necessary precaution.

During the evaluation, the affected individual is asked about recent illnesses, accidents, infections, and any other symptoms. A visual exam of the ears, throat, and sinus is done, and hearing is tested. The extent of the symptoms is assessed by grading the symmetry of the face at rest and during voluntary movements such as wrinkling the forehead, puckering the lips, and closing the affected eye. Involuntary movements are assessed in combination with the voluntary movements. Neurologic exam is done to rule out involvement of other parts of the nervous system.

Blood tests and sometimes a cerebrospinal fluid (CSF) analysis may be needed. The results of these tests help determine the presence of a bacterial or viral infection or an inflammatory disease. Electrophysiological tests such as electromyography and nerve conduction study, in which a muscle or nerve is artificially stimulated, may be used to assess the condition of facial muscles and the facial nerve, especially if paralysis is severe. Radiological tests may also be included, such as an x ray, magnetic resonance imaging (MRI), and computed tomography (CT).

Once all other possibilities are exhausted, a diagnosis of Bell's palsy is made. During the next few weeks, the patient is carefully assessed. If facial movement, even a small amount, has not returned within 3–4 months, the diagnosis of Bell's palsy may need to be reevaluated.

Treatment team

The patient's primary care provider may be the initial contact; further consultation may be obtained from a neurologist and/or an ophthalmologist. Physical therapists may help with pain issues and regaining function.

Treatment

In 2013, the American Academy of Otolaryngology updated its recommendations for treatment of Bell's palsy. The 2013 recommendations are for the use of corticosteroids (prednisone) within 72 hours of onset of symptoms, with antiviral drugs (e.g., acyclovir, valacyclovir) added to the corticosteroid treatment if the suspected cause of the palsy is viral.

Patients who have severe paralysis and do not show improvement may be candidates for facial nerve decompression surgery, although the need for this surgery is rare.

The need to protect the affected eye is universally promoted. Since the individual may not be able to lower the affected eyelid, the eye may become dry, particularly at night. Excessive dryness can damage the cornea. Daytime treatment includes artificial tears and may include an eye patch or other protective measures. Nighttime treatment involves a more intense effort at keeping the eye protected. Eye lubricants or viscous ointments, along with taping the eye shut, are frequently recommended.

In cases of permanent nerve damage, cosmetic treatment options such as therapeutic injections of botulism toxin (Botox) or surgery may be suggested.

WWW.BOOKBAZ.IR

KEY TERMS

Antiviral—A drug that prevents viruses from replicating and therefore spreading infection.

Computed tomography (CT)—Cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Electromyography—A recording of the electrical activity generated in the muscle.

Facial nerve—A cranial nerve that controls the muscles in the face.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Nerve conduction velocity—A recording of how well a nerve conducts electrical impulses.

Steroid—A drug used to reduce swelling and fluid accumulation.

Prognosis

Most individuals with Bell's palsy begin to notice improvement in their condition within 2–3 weeks of the symptoms' onset. At least 80% of them will be fully recovered within three months. Among the other 20% of afflicted individuals, symptoms may take longer to resolve or they may be permanent. Individuals suffering permanent nerve damage may not regain control of the muscles on the affected side of the face. These muscles may remain weak or paralyzed. As the nerve recovers, muscles may experience involuntary facial twitches or spasms that accompany normal facial expressions.

Bence Jones protein test

Definition

Bence Jones proteins are small proteins (light chains of immunoblobulin) found in the urine. Testing for these proteins is done to diagnose and monitor **multiple myeloma** and other similar diseases.

Purpose

Bence Jones proteins are considered the first tumor marker. A tumor marker is a substance, made by the body, that is linked to a certain cancer, or malignancy. Bence Jones proteins are made by plasma cells, a type of white blood cell. The presence of these proteins in a person's urine is associated with a malignancy of plasma cells.

Multiple myeloma, a tumor of plasma cells, is the disease most often linked with Bence Jones proteins. The amount of Bence Jones proteins in the urine indicates how much tumor is present. Physicians use Bence Jones proteins testing to diagnose the disease as well as to check how well the disease is responding to treatment.

Other diseases involving cancerous or excessive growth of plasma cells or cells similar to plasma cells can cause Bence Jones proteins in the urine. These diseases include: Waldenström's macroglobulinemia, some lymphomas and leukemias, osteogenic sarcoma, cryoglobulinemia, malignant B-cell disease, **amyloidosis**, light chain disease, and cancer that has spread to bone.

Description

Urine is the best specimen in which to look for Bence Jones proteins. Proteins are usually too large to move through a healthy kidney, from the blood into the urine. Bence Jones proteins are an exception. They

KEY TERMS

Bence Jones protein—Small protein, composed of a light chain of immunoglobulin, made by plasma cells.

Multiple myeloma—A tumor of the plasma cells.

Plasma cells—A type of white blood cell.

are small enough to move quickly and easily through the kidney into the urine.

A routine **urinalysis** will not detect Bence Jones proteins. There are several methods used by laboratories to detect and measure these proteins. The classic Bence Jones reaction involves heating urine to 140°F (60°C). At this temperature, the Bence Jones proteins will clump. The clumping disappears if the urine is further heated to boiling and reappears when the urine is cooled. Other clumping procedures using salts, acids, and other chemicals are also used to detect these proteins. These types of test will reveal whether or not Bence Jones proteins are present, but not how much is present.

A more complex procedure is done to measure the exact amount of Bence Jones proteins. This procedure—immunoelectrophoresis—is usually done on urine that has been collected for 24 hours.

The test is covered by insurance when medically necessary. Results are usually available within several days.

Preparation

Urine is usually collected throughout a 24-hour time period. A person is given a large container in which to collect the urine. The urine should be refrigerated until it is brought to the laboratory or physician's office.

Results

Bence Jones proteins normally are not present in the urine.

Abnormal results

Bence Jones proteins are present in 50–80% of people with multiple myeloma. People with other malignancies also can have a positive Bence Jones protein test, but less frequently.

Certain nonmalignant diseases, such as **rheumatoid arthritis**, **systemic lupus erythematosus**, and chronic **renal insufficiency**, can have Bence Jones proteins in the urine. High doses of penicillin or **aspirin** before collecting the urine can give a false positive result.

Bender-Gestalt test

Definition

The Bender Visual Motor Gestalt test (or Bender-Gestalt test) is a psychological assessment used to evaluate visual-motor functioning, visual-perceptual skills, neurological impairment, and emotional disturbances in children and adults ages three and older.

Purpose

The Bender-Gestalt is used to evaluate visual-motor maturity and to screen children for developmental delays. The test is also used to assess brain damage and neurological deficits. Individuals who have suffered a **traumatic brain injury** may be given the Bender-Gestalt as part of a battery of neuropsychological measures, or tests.

The Bender-Gestalt is sometimes used in conjunction with other personality tests to determine the presence of emotional and psychiatric disturbances such as **schizophrenia**.

Precautions

Psychometric testing requires a clinically trained examiner. The Bender Visual Motor Gestalt Test should be administered and interpreted by a trained psychologist or psychiatrist. The Bender-Gestalt should always be employed as only one element of a complete battery of psychological or developmental tests, and should never be used alone as the sole basis for a diagnosis.

Description

The original Bender Visual Motor Gestalt test was developed in 1938 by psychiatrist Lauretta Bender. There are several different versions of the Bender-

WWW.BOOKBAZ.IR

KEY TERMS

Neuropsychological test—A test or assessment given to diagnose a brain disorder or disease.

Perseveration—A response repeated persistently response after the cause of the response has been or a response that continues to different stimuli.

Visual-motor skills—Hand-eye coordination; in the Bender-Gestalt test, visual-motor skills are measured by the subject's ability to accurately perceive and then reproduce figures.

Visual-perceptual skills—The capacity of the mind and the eye to "see" something as it objectively exists.

Gestalt available today (i.e., the Bender-Gestalt test; Modified Version of the Bender-Gestalt test for Preschool and Primary School Children; the Hutt Adaptation of the Bender-Gestalt test; the Bender Visual Motor Gestalt test for Children; the Bender-Gestalt test for Young Children; the Watkins Bender-Gestalt Scoring System; the Canter Background Interference Procedure for the Bender-Gestalt test). All use the same basic test materials, but vary in their scoring and interpretation methods.

The standard Bender Visual Motor Gestalt test consists of nine figures, each on its own 3 × 5 card. An examiner presents each figure to the test subject one at a time and asks the subject to copy it onto a single piece of blank paper. The only instruction given to the subject is that he or she should make the best reproduction of the figure possible. The test is not timed, although standard administration time is typically 10–20 minutes. After testing is complete, the results are scored based on accuracy and organization. Interpretation depends on the form of the test in use. Common features considered in evaluating the drawings are rotation, distortion, symmetry, and perseveration. As an example, a patient with frontal lobe injury may reproduce the same pattern over and over (perseveration).

The Bender-Gestalt can also be administered in a group setting. In group testing, the figures are shown to test subjects with a slide projector, in a test booklet, or on larger versions of the individual test cards. Both the individual and group-administered Bender-Gestalt evaluation may take place in either an outpatient or hospital setting. Patients should check with their insurance plans to determine if these or other mental health services are covered.

Results

Children normally improve in this test as they age, but, because of the complexity of the scoring process, results for the Bender-Gestalt should only be interpreted by a clinically trained psychologist or psychiatrist.

Benzodiazepines

Definition

Benzodiazepines are medicines that help relieve nervousness, tension, and other symptoms by slowing the central nervous system.

Purpose

Benzodiazepines are a class of **antianxiety drugs**. While **anxiety** is a normal response to stressful situations, some people have unusually high levels of anxiety that can interfere with everyday life. For these people, benzodiazepines can help bring their feelings under control. The medicine can also relieve troubling symptoms of anxiety, such as pounding heartbeat, breathing problems, irritability, nausea, and faintness.

KEY TERMS

Anxiety—Worry or tension in response to real or imagined stress, danger, or dreaded situations. Physical reactions, such as fast pulse, sweating, trembling, fatigue, and weakness may accompany anxiety.

Asthma—A disease in which the air passages of the lungs to narrow, leading to wheezing, shortness of breath, and chest tightness.

Bronchitis—Inflammation of mucous membrane of the bronchial tubes, causing bronchospasm and coughing.

Central nervous system—The brain and spinal cord.

Chronic—A word used to describe a long-lasting condition. Chronic conditions often develop gradually and involve slow changes.

Emphysema—An irreversible lung disease in which breathing becomes increasingly difficult.

Epilepsy—A brain disorder with symptoms that include seizures.

Glaucoma—A condition in which pressure in the eye is abnormally high. If not treated, glaucoma may lead to blindness.

Physicians may sometimes prescribe these drugs for other conditions, such as **muscle spasms**, **epilepsy** and other seizure disorders, **phobias**, **panic disorder**, withdrawal from alcohol, and sleeping problems. However, this medicine should not be used every day for sleep problems that last more than a few days. If used this way, the drug loses its effectiveness within a few weeks.

Description

The family of antianxiety drugs known as benzodiazepines includes alprazolam (Xanax), chlordiazepoxide (Librium), diazepam (Valium), and lorazepam (Ativan). These medicines take effect fairly quickly, starting to work within an hour after they are taken. Benzodiazepines are available only with a physician's prescription and are available in tablet, capsule, liquid, or injectable forms.

Recommended dosage

The recommended dosage depends on the type of benzodiazepine, its strength, and the condition for which it is being taken. Doses may be different for different people. Check with the physician who prescribed the drug or the pharmacist who filled the prescription for the correct dosage.

Always take benzodiazepines exactly as directed. Never take larger or more frequent doses, and do not take the drug for longer than directed. If the medicine does not seem to be working, check with the physician who prescribed it. *Do not increase the dose or stop taking the medicine unless the physician says to do so.* Stopping the drug suddenly may cause withdrawal symptoms, especially if it has been taken in large doses or over a long period. People who are taking the medicine for seizure disorders may have seizures if they stop taking it suddenly. If it is necessary to stop taking the medicine, check with a physician for directions on how to stop. The physician may recommend tapering down gradually to reduce the chance of withdrawal symptoms or other problems.

Precautions

Seeing a physician regularly while taking benzodiazepines is important, especially during the first few months of treatment. The physician will check to make sure the medicine is working as it should and will note unwanted side effects.

People who take benzodiazepines to relieve nervousness, tension, or symptoms of panic disorder should check with their physicians every two to three months to make sure they still need to keep taking the medicine.

Patients who are taking benzodiazepines for sleep problems should check with their physicians if they are not sleeping better within 7–10 days. Sleep problems that last longer than this may be a sign of another medical problem.

People who take this medicine to help them sleep may have trouble sleeping when they stop taking the medicine. This effect should last only a few nights.

Some people, especially older people, feel drowsy, dizzy, lightheaded, or less alert when using benzodiazepines. The drugs may also cause clumsiness or unsteadiness. When the medicine is taken at bedtime, these effects may even occur the next morning. Anyone who takes these drugs should not drive, use machines or do anything else that might be dangerous until they have found out how the drugs affect them.

Benzodiazepines may also cause behavior changes in some people, similar to those seen in people who act

WWW.BOOKBAZ.IR

Myasthenia gravis—A chronic disease with symptoms that include muscle weakness and sometimes paralysis.

Panic disorder—A disorder in which people have sudden and intense attacks of anxiety in certain situations. Symptoms such as shortness of breath, sweating, dizziness, chest pain, and extreme fear often accompany the attacks.

Phobia—An intense, abnormal, or illogical fear of something specific, such as heights or open spaces.

Porphyria—A disorder in which porphyrins build up in the blood and urine.

Porphyrin—A type of pigment found in living things.

Seizure—A sudden attack, spasm, or convulsion.

Sleep apnea—A condition in which a person temporarily stops breathing during sleep.

Withdrawal symptoms—A group of physical or mental symptoms that may occur when a person suddenly stops using a drug to which he or she has become dependent.

differently when they drink alcohol. More extreme changes, such as confusion, agitation, and **hallucinations**, also are possible. Anyone who starts having strange or unusual thoughts or behavior while taking this medicine should get in touch with his or her physician.

Because benzodiazepines work on the central nervous system, they may add to the effects of alcohol and other drugs that slow down the central nervous system, such as **antihistamines**, cold medicine, allergy medicine, sleep aids, medicine for seizures, tranquilizers, some **pain** relievers, and **muscle relaxants**. They may also add to the effects of anesthetics, including those used for dental procedures. These effects may last several days after treatment with benzodiazepines ends. *The combined effects of benzodiazepines and alcohol or other CNS depressants (drugs that slow the central nervous system) can be very dangerous, leading to unconsciousness or, rarely, even death*. Anyone taking benzodiazepines should not drink alcohol and should check with his or her physician before using any CNS depressants. *Taking an overdose of benzodiazepines can also cause unconsciousness and possibly death. Anyone who shows signs of an overdose or of the effects of combining benzodiazepines with alcohol or other drugs should get immediate emergency help*. Warning signs include slurred speech or confusion, severe drowsiness, staggering, and profound weakness.

Some benzodiazepines may change the results of certain medical tests. Before having medical tests, anyone taking this medicine should alert the healthcare professional in charge.

Children are generally more sensitive than adults to the effects of benzodiazepines. This sensitivity may increase the chance of side effects.

Older people are more sensitive than younger adults to the effects of this medicine and may be at greater risk for side effects. Older people who take these drugs to help them sleep may be drowsy during the day. Older people also increase their risk of falling and injuring themselves when they take these drugs.

Special conditions

People with certain medical conditions or who are taking certain other medicines can have problems if they take benzodiazepines. Before taking these drugs, be sure to let the physician know about any of these conditions:

ALLERGIES. Anyone who has had unusual reactions to benzodiazepines or other mood-altering drugs in the past should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. Some benzodiazepines increase the likelihood of **birth defects**. Using these medicines during **pregnancy** may also cause the baby to become dependent on them and to have withdrawal symptoms after birth. When taken late in pregnancy or around the time of labor and delivery, these drugs can cause other problems in the newborn baby, such as weakness, breathing problems, slow heartbeat, and body temperature problems.

BREASTFEEDING. Benzodiazepines may pass into breast milk and cause problems in babies whose mothers taken the medicine. These problems include drowsiness, breathing problems, and slow heartbeat. Women who are **breastfeeding** their babies should not use this medicine without checking with their physicians.

OTHER MEDICAL CONDITIONS. Before using benzodiazepines, people with any of these medical problems should make sure their physicians are aware of their conditions:

- current or past drug or alcohol abuse
- depression
- severe mental illness
- epilepsy or other seizure disorders
- swallowing problems
- chronic lung disease such as emphysema, asthma, or chronic bronchitis
- kidney disease
- liver disease
- brain disease
- glaucoma
- hyperactivity
- myasthenia gravis
- porphyria
- sleep apnea

USE OF CERTAIN MEDICINES. Taking benzodiazepines with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

Side effects

The most common side effects are **dizziness**, lightheadedness, drowsiness, clumsiness, unsteadiness, and slurred speech. These problems usually go away as the body adjusts to the drug and do not require medical treatment unless they persist or they interfere with normal activities.

More serious side effects are not common, but may occur. If any of the following side effects occur, check with the physician who prescribed the medicine as soon as possible:

- behavior changes
- memory problems
- difficulty concentrating
- confusion
- depression
- seizures (convulsions)
- hallucinations
- sleep problems
- increased nervousness, excitability, or irritability
- involuntary movements of the body, including the eyes
- low blood pressure
- unusual weakness or tiredness
- skin rash or itching
- unusual bleeding or bruising
- yellow skin or eyes
- sore throat
- sores in the mouth or throat
- fever and chills

Patients who take benzodiazepines for a long time or at high doses may notice side effects for several weeks after they stop taking the drug. They should check with their physicians if these or other troublesome symptoms occur:

- irritability
- nervousness
- sleep problems

Other rare side effects may occur. Anyone who has unusual symptoms during or after treatment with benzodiazepines should get in touch with his or her physician.

Interactions

Benzodiazepines may interact with a variety of other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes benzodiazepines should let the physician know all other medicines he or she is taking. Among the drugs that may interact with benzodiazepines are:

- Central nervous system (CNS) depressants such as medicine for allergies, colds, hay fever, and asthma; sedatives; tranquilizers; prescription pain medicine; muscle relaxants; medicine for seizures; sleep aids; barbiturates; and anesthetics.

Medicines other than those listed above may interact with benzodiazepines. Be sure to check with a physician or pharmacist before combining benzodiazepines with any other prescription or nonprescription (over-the-counter) medicine.

Bereavement

Definition

Bereavement refers to the period of mourning and grief following the death of a beloved person or animal. The English word *bereavement* comes from an ancient Germanic root word meaning "to rob" or "to seize by violence." *Mourning* is the word that is used to describe the public rituals or symbols of bereavement, such as holding funeral services, wearing black clothing, closing a place of business temporarily, or lowering a flag to half mast. *Grief* refers to one's personal experience of loss; it includes physical symptoms as well as emotional and spiritual reactions to the loss. While public expressions of mourning are usually time-limited, grief is a process that takes most people several months or years to work through.

Students gathered around a memorial on a college campus, honoring and grieving slain students. *(Scott Olson/Getty Images News/Getty Images.)*

Description

Bereavement is a highly individual as well as a complex experience. It is increasingly recognized that no two people respond the same way to the losses associated with the death of a loved one. People's reactions to a death are influenced by such factors as ethnic or religious traditions; personal beliefs about life after death; the type of relationship ended by death (relative, friend, colleague, etc.); the cause of death; the person's age at death; whether the death was sudden or expected; and many others. In addition, the death of a loved one inevitably confronts adults (and older adolescents) with the fact that they too will die. As a result of this complexity, most doctors and other counselors advise people to trust their own feelings about bereavement and grieve in the way that seems most helpful to them.

It is also increasingly understood that people can experience bereavement with regard to other losses. Some examples of these so-called "silent losses" include miscarriages in early **pregnancy**, the death of a child in the womb shortly before birth, or the news that a loved one has Alzheimer's disease or another illness that slowly destroys their personality. In addition, many counselors recognize that bereavement has two dimensions, the actual loss and the symbolic losses. For example, a person whose teenage son or daughter is killed in an accident suffers a series of symbolic losses—knowing that their child will never graduate from high school, get married, or have children—as well as the actual loss of the adolescent to death.

Causes and symptoms

Causes

The immediate cause of bereavement is usually the death of a loved friend or relative. There are a number of situations, however, that can affect or prolong the grief process:

- The relationship with the dead person was a source of pain rather than love and support. Examples would include an abusive parent or spouse.
- The person died in military service or in a natural, transportation, or workplace disaster. Bereavement in these cases is often made more difficult by intrusive news reporters as well as anxiety over the loved one's possible physical or mental suffering prior to death.
- The person was murdered. Survivors of homicide victims often find the criminal justice system as well as the media frustrating and upsetting.

KEY TERMS

Bibliotherapy—The use of books (usually self-help or problem-solving works) to improve one's understanding of personal problems and/or to heal painful feelings.

Biofield healing—A general term for a group of alternative therapies based on the belief that the human body is surrounded by an energy field (or aura) that reflects the condition of the person's body and spirit. Rebalancing or repairing the energy field is thought to bring about healing in mind and body. Reiki, therapeutic touch, polarity balancing, Shen therapy, and certain forms of color therapy are considered forms of biofield healing.

Complicated grief—An abnormal response to bereavement that includes unrelieved yearning for the dead person, the complete loss of previous positive beliefs or worldviews, and a general inability to function.

Disenfranchised grief—Grief that cannot be openly expressed because the death or other loss cannot be publicly acknowledged.

Euthanasia—The act of putting individuals or animals to death painlessly or allowing them to die by withholding medical services, usually because they have a painful and incurable disease.

Mourning—The public expression of bereavement; it may include funerals and other rituals, special clothing, and symbolic gestures.

Regression—A return to earlier, particularly infantile, patterns of thought and behavior.

Thanatology—The medical, psychological, or legal study of death and dying.

Traumatic grief—Grief resulting from the loss of a loved one in a traumatic situation (natural or transportation disaster, act of terrorism, or mass murder, etc.).

- The person is missing and presumed dead but their death has not been verified. As a result, friends and relatives may alternate between grief and hope that the person is still alive.
- The person committed suicide. Survivors may feel guilt over their inability to foresee or prevent the suicide, shame that the death was self-inflicted, or anger at the person who committed suicide.
- The relationship with the dead person cannot be openly acknowledged. This situation often leads to what is called disenfranchised grief. The most common instances are sexual relationships that have been kept secret for the sake of spouses or other family members.
- The loved one was an animal rather than a human being. Western societies are only beginning to accept that adults as well as children can grieve for a dead animal; many adults still feel that there is "something wrong" about grieving for their pet. The question of euthanasia may be an additional source of sorrow; even when the pet is terminally ill, many people are very uneasy about making the decision to end its life.

Symptoms

Bereavement typically affects a person's physical well-being as well as emotions. Common symptoms of grief include changes in appetite and weight, **fatigue**, **insomnia** and other sleep disturbances, loss of interest in sex, low energy levels, **nausea and vomiting**, chest or throat **pain**, and **headache**. People who have lost a loved one in traumatic circumstances may have symptoms of **post-traumatic stress disorder**, such as an exaggerated startle response, visual or auditory **hallucinations**, or high levels of muscular tension.

Doctors and other counselors have identified four stages or phases in uncomplicated bereavement:

- Shock, disbelief, feelings of numbness. This initial phase lasts about two weeks, during which the bereaved person finally accepts the reality of the loved one's death.
- Suffering the pain of grief. This phase typically lasts for several months. Some people undergo a mild temporary depression about six months after the loved one's death.
- Adjusting to life without the loved one. In this phase of bereavement, survivors may find themselves taking on the loved one's roles and responsibilities as well as redefining their own identities.
- Moving forward with life, forming new relationships, and having positive expectations of the future. Most people reach this stage within one to two years after the loved one's death.

BEREAVEMENT IN CHILDREN. Children do not experience bereavement in the same way as adolescents and adults. Preschool children usually do not understand death as final and irreversible, and may talk or act as if the dead pet or family member will wake up or come

WWW.BOOKBAZ.IR

back. Children between the ages of five and nine are better able to understand the finality of death, but they tend to assume it will not affect them or their family. They are likely to be shocked and severely upset by a death in their immediate family. In addition to the physical disturbances that bereaved adults often experience, children sometimes begin to act like infants again (wanting bottle feeding, using baby talk, etc.) This pattern of returning to behaviors characteristic of an earlier life stage is called regression.

TRAUMATIC AND COMPLICATED GRIEF. Since the early 1990s, thanatologists (doctors and other counselors who specialize in issues related to **death and dying**) have identified two types of grief that do not resolve normally with the passage of time. Traumatic grief is defined as grief resulting from a sudden traumatic event that involves violent suffering, mutilation, and/or multiple deaths; appears to be random or preventable; and often involves the survivor's own brush with death. The symptoms of traumatic grief are similar to those of post-traumatic **stress** disorder (PTSD). Such events as the terrorist attacks of September 11, 2001; the East Asian tsunami of December 2004; and airplane crashes or other transportation disasters may produce traumatic grief in survivors.

In contrast to traumatic grief, complicated grief does not necessarily result from a specific type of event but rather refers to an abnormally intense and prolonged response to bereavement. While most people are able to move through a period of bereavement and recover a sense of purpose and meaning in life, people with complicated grief feel as if their entire worldview has been shattered. They cannot stop thinking of the dead person, long to be with him or her, and may feel that part of them died along with the loved one. They sometimes start acting like the deceased person, mimicking the symptoms of his or her illness, behaving in reckless ways, talking about "joining" the loved one, or refusing to accept the reality of the death. In general they are unable to function normally. Complicated grief should not be regarded as simply a subtype of clinical depression; the two conditions may coexist or overlap in some patients but are nonetheless distinct entities.

Diagnosis

Bereavement is considered a normal response to a death or other loss. A doctor who suspects that a patient is suffering from traumatic or complicated grief, however, may use various psychological inventories or questionnaires to see whether the patient meets the criteria for PTSD, major depression, or **acute stress disorder**. In addition, there are several specific questionnaires to help diagnose complicated grief.

Treatment

Most people do not require formal treatment for bereavement. However, many people choose to participate in support groups for recently bereaved people or hospice follow-up programs for relatives of patients who died in that hospice. Bereavement support groups are particularly helpful in guiding members through such common but painful problems as disposing of the dead person's possessions, celebrating holidays without the loved one, coping with anniversaries, etc.

Traumatic grief is usually treated in the same way as post-traumatic stress, with temporary use of medications to control sleep disturbances and **anxiety** symptoms along with long-term **psychotherapy**. Those suffering from traumatic grief may also be referred to support groups of people dealing with the same type of sudden and violent loss. Complicated grief is usually managed with a combination of group and individual psychotherapy.

Alternatives

Alternative therapies that have been reported to help with the sleep disturbances and other physical symptoms of bereavement include prayer and **meditation**; such movement therapies as **yoga** and tai chi; **therapeutic touch**, **Reiki**, and other forms of biofield healing; bibliotherapy and journaling; **music therapy**; **art therapy**; **hydrotherapy**; and **massage therapy**.

Prognosis

Most people move through the stages of the normal grief process within several months to two years, depending on the length and closeness of the relationship. Traumatic grief and complicated grief, however, may take three years or longer to resolve, even with appropriate treatment.

Prevention

Bereavement is considered a normal response to death and loss, which are universal human experiences. It should ordinarily be allowed to run its course; most counselors maintain that trying to stifle or cut short the grief process is more likely to cause emotional problems later on than to prevent them.

Berger's disease *see* **Idiopathic primary renal hematuric/proteinuric syndrome**

Beriberi

Definition

Beriberi is a disease caused by a deficiency of thiamine (vitamin B_1) that affects many systems of the body, including the muscles, heart, nerves, and digestive system. Beriberi literally means "I can't, I can't" in Singhalese, which reflects the crippling effect it has on its victims. It is common in parts of southeast Asia, where white rice is the main food. In the United States, beriberi is primarily seen in people with chronic **alcoholism**.

Description

Beriberi puzzled medical experts for years as it ravaged people of all ages in Asia. Doctors thought it was caused by something in food. Not until the early 1900s did scientists discover that rice bran, the outer covering that was removed to create the polished white rice preferred by Asians, actually contained something that prevented the disease. Thiamine was the first vitamin identified. In the 1920s, extracts of rice polishings were used to treat the disease.

In adults, there are different forms of beriberi, classified according to the body systems most affected. Dry beriberi involves the nervous system; wet beriberi affects the heart and circulation. Both types usually occur in the same patient, with one set of symptoms predominating.

A less common form of cardiovascular, or wet beriberi, is known as "shoshin." This condition involves a rapid appearance of symptoms and acute **heart failure**. It is highly fatal and is known to cause sudden death in young migrant laborers in Asia whose diet consists of white rice.

Cerebral beriberi, also known as Wernicke-Korsakoff syndrome, usually occurs in chronic alcoholics and affects the central nervous system (brain and

WWW.BOOKBAZ.IR

KEY TERMS

B vitamins—This family of vitamins consists of thiamine (B_1), riboflavin (B_2), niacin (B_3), pantothenic acid (B_5), pyridoxine (B_6), biotin, folic acid (B_9), and cobalamin (B_{12}). They are interdependent and involved in converting glucose to energy.

Coenzyme—A substance needed by enzymes to produce many of the reactions in energy and protein metabolism in the body.

Edema—An excess accumulation of fluid in the cells and tissues.

Enzyme—A protein that acts as a catalyst to produce chemical changes in other substances without being changed themselves.

Metabolism—All the physical and chemical changes that take place within an organism.

Peripheral neuropathy—A disease affecting the portion of the nervous system outside the brain and spinal chord. One or more nerves can be involved, causing sensory loss, muscle weakness and shrinkage, and decreased reflexes.

Thiamine pyrophosphate (TPP)—The coenzyme containing thiamine that is essential in converting glucose to energy.

spinal cord). It can be caused by a situation that aggravates a chronic thiamine deficiency, like an alcoholic binge or severe **vomiting**.

Infantile beriberi is seen in breastfed infants of thiamine-deficient mothers, who live in developing nations.

Although severe beriberi is uncommon in the United States, less severe thiamine deficiencies do occur. About 25% of all alcoholics admitted to a hospital in the United States show some evidence of thiamine deficiency.

Causes and symptoms

Thiamine is one of the B **vitamins** and plays an important role in energy metabolism and tissue building. It combines with phosphate to form the coenzyme *thiamine pyrophosphate (TPP)*, which is essential in reactions that produce energy from glucose or that convert glucose to fat for storage in the tissues. When there is not enough thiamine in the diet, these basic energy functions are disturbed, leading to problems throughout the body.

Special situations, such as an over active metabolism, prolonged **fever**, **pregnancy**, and **breastfeeding**, can increase the body's thiamine requirements and lead to symptoms of deficiency. Extended periods of **diarrhea** or chronic **liver disease** can result in the body's inability to maintain normal levels of many nutrients, including thiamine. Other persons at risk are patients with kidney failure on dialysis and those with severe digestive problems who are unable to absorb nutrients. Alcoholics are susceptible because they may substitute alcohol for food and their frequent intake of alcohol decreases the body's ability to absorb thiamine.

The following systems are most affected by beriberi:

- Gastrointestinal system. When the cells of the smooth muscles in the digestive system and glands do not get enough energy from glucose, they are unable to produce more glucose from the normal digestion of food. There is a loss of appetite, indigestion, severe constipation, and a lack of hydrochloric acid in the stomach.
- Nervous system. Glucose is essential for the central nervous system to function normally. Early deficiency symptoms are fatigue, irritability, and poor memory. If the deficiency continues, there is damage to the peripheral nerves that causes loss of sensation and muscle weakness, which is called peripheral neuropathy. The legs are most affected. The toes feel numb and the feet have a burning sensation; the leg muscles become sore and the calf muscles cramp. The individual walks unsteadily and has difficulty getting up from a squatting position. Eventually, the muscles shrink (atrophy) and there is a loss of reflexes in the knees and feet; the feet may hang limp (footdrop).
- Cardiovascular system. There is a rapid heartbeat and sweating. Eventually the heart muscle weakens. Because the smooth muscle in the blood vessels is affected, the arteries and veins relax, causing swelling, known as edema, in the legs.
- Musculoskeletal system. There is widespread muscle pain caused by the lack of TPP in the muscle tissue.

Infants who are breastfed by a thiamine-deficient mother usually develop symptoms of deficiency between the second and fourth month of life. They are pale, restless, unable to sleep, prone to diarrhea, and have muscle wasting and **edema** in their arms and

legs. They have a characteristic, sometimes silent, cry and develop heart failure and nerve damage.

Diagnosis

A **physical examination** will reveal many of the early symptoms of beriberi, such as **fatigue**, irritation, nausea, **constipation**, and poor memory, but the deficiency may be difficult to identify. Information about the individual's diet and general health is also needed.

There are many biochemical tests based on thiamine metabolism or the functions of TPP that can detect a thiamine deficiency. Levels of thiamine can be measured in the blood and urine and will be reduced if there is a deficiency. The urine can be collected for 24 hours to measure the level of thiamine excreted. Another reliable test measures the effect of TPP on red blood cell activity since all forms of beriberi affect the metabolism of red blood cells.

An electroencephalogram (EEG), which measures electrical activity in the brain, may be done to rule out other causes of neurologic changes. Observing improvements in the patient after giving thiamine supplements will also confirm the diagnosis.

Treatment

Treatment with thiamine reverses the deficiency in the body and relieves most of the symptoms. Severe thiamine deficiency is treated with high doses of thiamine given by injection into a muscle (intramuscular) or in a solution that goes into a vein (intravenously) for several days. Then smaller doses can be given either by injection or in pill form until the patient recovers. Usually there are other deficiencies in the B vitamins that will also need treatment.

The cardiovascular symptoms of wet beriberi can respond to treatment within a few hours if they are not too severe. Heart failure may require additional treatment with **diuretics** that help eliminate excess fluid and with heart-strengthening drugs like digitalis.

Recovery from **peripheral neuropathy** and other symptoms of dry beriberi may take longer and patients frequently become discouraged. They should stay active; **physical therapy** will also help in recovery.

Infantile beriberi is treated by giving thiamine to both the infant and the breastfeeding mother until levels are normal.

In Wernicke-Korsakoff syndrome, thiamine should be given intravenously or by injection at first because the intestinal absorption of thiamine is probably impaired and the patient is very ill. Most of the symptoms will be relieved by treatment, though there may be residual **memory loss**.

Excess thiamine is excreted by the body in the urine, and negative reactions to too much thiamine are rare. Thiamine is unstable in alkali solutions, so it should not be taken with **antacids** or **barbiturates**.

Alternatives

Alternative treatments for beriberi deal first with correcting the thiamine deficiency. As in conventional treatments, alternative treatments for beriberi **stress** a diet rich in foods that provide thiamine and other B vitamins, such as brown rice, whole grains, raw fruits and vegetables, legumes, seeds, nuts, and yogurt. Drinking more than one glass of liquid with a meal should be avoided, since this may wash out the vitamins before they can be absorbed by the body. Thiamine should be taken daily, with the dose depending on the severity of the disease. Additional supplements of B vitamins, a multivitamin and mineral complex, and Vitamin C are also recommended. Other alternative therapies may help relieve the person's symptoms after the thiamine deficiency is corrected.

Prognosis

Beriberi is fatal if not treated and the longer the deficiency exists, the sicker the person becomes. Most of the symptoms can be reversed and full recovery is possible when thiamine levels are returned to normal and maintained with a balanced diet and vitamin supplements as needed.

Prevention

A balanced diet containing all essential nutrients will prevent a thiamine deficiency and the development of beriberi. People who consume large quantities of junk food like soda, pretzels, chips, candy, and high carbohydrate foods made with unenriched flours may be deficient in thiamine and other vital nutrients. They may need to take vitamin supplements and should improve their **diets**.

Dietary requirements

The body's requirements for thiamine are tied to carbohydrate metabolism and expressed in terms of total intake of calories. The current recommended dietary allowances (RDA) are 0.5 mg for every 1,000 calories, with a minimum daily intake of 1 mg even for those who eat fewer than 2,000 calories in a day. The RDA for children and teenagers is the same as for

WWW.BOOKBAZ.IR

adults: 1.4 mg daily for males over age eleven, and 1.1 mg for females. During pregnancy, an increase to 1.5 mg daily is needed. Because of increased energy needs and the secretion of thiamine in breast milk, breast-feeding mothers need 1.5 mg every day. In infants, 0.4 mg is advised.

Food sources

The best food sources of thiamine are lean pork, beef, liver, brewer's yeast, peas and beans, whole or enriched grains, and breads. The more refined the food, as in white rice, white breads, and some cereals, the lower the thiamine. Many food products are enriched with thiamine, along with riboflavin, niacin, and iron, to prevent dietary deficiency.

During the milling process, rice is polished and all the vitamins in the exterior coating of bran are lost. Boiling the rice before husking preserves the vitamins by distributing them throughout the kernel. Food enrichment programs have eliminated beriberi in Japan and the Phillipines.

Like all B vitamins, thiamine is water soluble, which means it is easily dissolved in water. It will leach out during cooking in water and is destroyed by high heat and overcooking.

Berry aneurysm *see* **Cerebral aneurysm**

Beryllosis

Definition

Beryllosis is lung inflammation caused by inhaling dust or fumes that contain the metallic element beryllium. Found in rocks, coal, soil, and volcanic dust, beryllium is used in the aerospace industry and in many types of manufacturing. Beryllosis occurs in both acute and chronic forms. In some cases, appearance of the disease may be delayed as much as 20 years after exposure to beryllium.

KEY TERMS

Beryllium—A steel-grey, metallic mineral used in the aerospace and nuclear industries and in a variety of manufacturing processes.

Chelation therapy—A treatment using chelating agents, compounds that surround and bind to target substances allowing them to be excreted from the body.

Corticosteroids—A group of anti-inflammatory drugs.

Description

In the 1930s, scientists discovered that beryllium could make fluorescent light bulbs last longer. During the following decade, the hard, grayish metal was identified as the cause of a potentially debilitating, sometimes deadly disease characterized by **shortness of breath** and inflammation, swelling, and scarring of the lungs.

The manufacture of fluorescent light bulbs is no longer a source of beryllium exposure, but serious health hazards are associated with any work environment or process in which beryllium fumes or particles become airborne. Working with pure beryllium, beryllium compounds (e.g., beryllium oxide), or beryllium alloys causes occupational exposure. So do jobs involving:

- electronics
- fiber optics
- manufacturing ceramics, bicycle frames, golf clubs, mirrors, and microwave ovens
- mining
- nuclear weapons and reactors
- reclaiming scrap metal
- space and atomic engineering
- dental and laboratory technology

Beryllium dust and fumes are classified as toxic air pollutants by the Environmental Protection Agency (EPA). It is estimated that 2–6% of workers exposed to these contaminants eventually develop berylliosis.

Causes and symptoms

Coughing, shortness of breath, and weight loss that begin abruptly can be a symptom of acute berylliosis. This condition is caused by beryllium air pollution that inflames the lungs making them rigid; it can affect the eyes and skin as well. People who have acute berylliosis

are usually very ill. Most recover, but some die of the disease.

Chronic berylliosis is an allergic reaction to long-term exposure to even low levels of beryllium dust or fumes. A systemic disease that causes formation of abnormal lung tissue and enlargement of the lymph nodes, chronic berylliosis also may affect other parts of the body. The symptoms of chronic berylliosis are largely the same as those seen in acute berylliosis, but they develop more slowly.

Diagnosis

Berylliosis is initially suspected if a patient with symptoms of the disease has a history of beryllium exposure. A chest x ray shows characteristic changes in the lungs. However, since these changes can resemble those caused by other lung diseases, further testing may be necessary.

The beryllium lymphocyte proliferation test (BeLPT), a blood test that can detect beryllium sensitivity (i.e., an allergic reaction to beryllium), is used to screen individuals at risk of developing berylliosis. When screening results reveal a high level of sensitivity, BeLPT is performed on cells washed from the lungs. This test is now considered the most definitive diagnostic test for berylliosis.

Treatment

Individuals with beryllium sensitivity or early-stage berylliosis should be transferred from tasks that involve beryllium exposure and regularly examined to determine whether the disease has progressed.

Acute berylliosis is a serious disease that occasionally may be fatal. Ventilators can help patients with acute berylliosis breathe. Prompt corticosteroid therapy is required to lessen lung inflammation.

Chronic beryllium disease is incurable. Corticosteroid therapy is often prescribed, but it is not certain that **steroids** can alter the progression of the disease, and they have no effect on scarring of lung tissue. Cleansing the lungs of beryllium is a slow process, so long-term therapy may be required. **Chelation therapy** is currently under investigation as a treatment for the disease.

Prognosis

Most patients with acute berylliosis recover fully 7–10 days after treatment begins, and the disease usually causes no after effects.

Patients whose lungs are severely damaged by chronic berylliosis may experience fatal **heart failure** because of the strain placed on the heart.

Prevention

liminating exposure to beryllium is the surest way to prevent berylliosis. Screening workers who are exposed to beryllium fumes or dust or who develop an allergic reaction to these substances is an effective way to control symptoms and prevent disease progression.

Beta blockers

Definition

Beta blockers are medicines that reduce the body's response to **stress** hormones, including adrenalin.

Purpose

Beta blockers lower heart rate and reduce the force of heart contractions. Beta blockers are used to help treat the following conditions:

- congestive heart failure
- chest pain (angina)
- high blood pressure
- irregular heart beat (arrhythmia)
- maintaining normal heart rhythm after treating rhythm disturbance

WWW.BOOKBAZ.IR

Beta blockers

Brand name (generic name)	Possible side effects
Betapace (sotalol)	Diarrhea, excessive tiredness, headache, muscle aches
Blocadren (timolol)	Coldness in hands and feet, dizziness, fatigue, headache, heartburn
Cartrol (carteolol)	Blurred vision, burning or stinging in eyes, sensitivity to light
Corgard (nadolol)	Excessive tiredness, lightheadedness
Inderal (propranolol)	Constipation, dizziness, fatigue, insomnia, upset stomach
Kerlone (betaxolol)	Diarrhea, heartburn, insomnia, joint pain, nausea, rash, strange dreams
Lopressor, Toprol XL (metoprolol)	Depression, dizziness, dry mouth, fatigue, nausea and vomiting, rash
Sectral (acebutolol)	Constipation, dizziness, fatigue, headache, muscle aches
Tenormin (atenolol)	Blurred vision, difficulty breathing, fainting, pallor, swelling of extremities, weight gain
Zebeta (bisoprolol)	Diarrhea, muscle aches, runny nose, vomiting
Ziac (bisoprolol/ hydrochlorothiazide)	Cough, fatigue, headache, lightheadedness

(Table by PreMediaGlobal. © Cengage Learning®)

- heart attack
- acute migraine headaches, and preventing future ones in some patients
- essential tremors
- some types of glaucoma
- performance anxiety (off-label)

Description

Beta blockers are available as capsules, tablets, liquids, eye drops, and injections.

Examples of beta blockers include atenolol (Tenormin), metoprolol (Lopressor), nadolol (Corgard), propranolol (Inderal), and timolol (Blocadren).

Recommended dosage

The recommended dose depends on the type and strength of drug used and the condition for which it is prescribed.

Beta blockers should be taken as directed and not stopped without consulting with a physician.

This medicine may take several weeks to noticeably lower blood pressure. It is important to take the medication exactly as directed.

Physicians may recommend that patients check their pulse before and after taking this medicine. If the pulse rate becomes too slow, circulation problems may result.

Precautions

Discontinuing beta blockers without medical advice may increase the risk of **heart attack**

Beta blockers antagonize the effects of **bronchodilators** used to treat **asthma** and **emphysema** and may interfere with treating those conditions.

These drugs may mask the effects of low blood sugar, like rapid heart rate, in diabetic patients.

Anyone taking beta blockers should seek advice from a pharmacist or physician before taking other prescription or over-the-counter medicine.

Anyone taking beta blockers should inform their healthcare professionals before having surgical or dental procedures or receiving emergency treatment.

People may feel drowsy, dizzy, or lightheaded when they start taking these drugs. They should not drive or use dangerous machines until they find how the drugs affect them.

Beta blockers may increase sensitivity to cold, especially in older people or people who have poor circulation. Anyone who takes these medicines should dress warmly in cold weather.

People with chest **pain** on exertion may not experience the same kinds of pain while taking these medications. They should seek advice from their physicians regarding safe levels of physical activity while taking these drugs.

Older people may be unusually sensitive to the effects of beta blockers.

Before starting to take beta blockers, treating physicians need to know what other medications and medical conditions their patients have.

Beta blockers may affect the way patients respond to their **allergies**.

DIABETES. Beta blockers may make blood sugar levels rise and may hide some symptoms of low blood sugar. Diabetic patients should discuss these possible problems with their physicians.

PREGNANCY. Atenolol, and possibly other beta blockers, crosses the placenta; babies born of pregnant women taking these drugs may be briefly affected.

BREASTFEEDING. Some beta blockers pass into breast milk and may cause low blood pressure and low pulse rates in nursing babies whose mothers take the drugs. Women who need to take beta blockers and who want to breastfeed should seek medical advice.

OTHER MEDICAL CONDITIONS. Patients with asthma and/or emphysema may be adversely affected by beta blocker medications and should monitor themselves carefully.

Beta blockers may reduce symptoms, especially rapid pulse, of an overactive thyroid.

Liver and kidney diseases may increase or prolong the effects of these drugs.

Beta blockers may also make the following medical conditions worse:

- normally slow heartbeat (bradycardia)
- Myasthenia gravis (chronic disease causing muscle weakness and possibly paralysis)
- psoriasis (itchy, scaly, red patches of skin)
- depression

Side effects

The most common side effects include:

- fatigue
- dizziness
- drowsiness
- lightheadedness
- decreased sexual desire
- cold hands
- trouble sleeping
- trouble breathing
- depression

Interactions

Beta blockers may interact with a number of medicines. Reactions may be minor or severe and affect the risks or side effects of either drug. Patients should discuss drugs they take with health providers before starting to take beta blockers.

Possible interactions include:

- The effects of both beta blockers and calcium channel blockers (Cardizem and Calan) increase when they are taken together.
- Phenothiazines (Thorazine and Mellaril) and beta blockers have a probable delayed interaction that may increase the effects of either or both drugs. This is particularly dangerous in elderly people.
- Barbiturates may reduce the effectiveness of beta blockers.
- Cimetidine (Tagamet) may reduce the effectiveness of beta blockers.
- Benadryl increases the effects of these drugs on the heart.
- If orange juice is drunk at the same time that beta blockers are taken, their effects may be reduced.
- Hydralazine (Apresoline) and beta blockers interact to increase the effects of both drugs.
- Haloperidol (Haldol) and beta blockers interact to increase the effects of both drugs.
- NSAIDs, non-steroidal anti inflammatory drugs (ibuprofen, naproxen, indomethacin), may decrease the effectiveness of beta blockers.
- Penicillins (Ampicillin) may reduce the effects of beta blockers.
- Salicylates (aspirin) may reduce the effects of beta blockers.

Beta$_2$-microglobulin test

Definition

Beta$_2$-microglobulin is a protein found on the surface of many cells. Testing is done primarily when evaluating a person for certain kinds of cancer affecting white blood cells including chronic lymphocytic leukemia, non-Hodgkin's lymphoma, and **multiple myeloma** or **kidney disease**.

Purpose

Beta$_2$-microglobulin is plentiful on the surface of white blood cells. Increased production or destruction of these cells causes Beta$_2$-microglobulin levels in the blood to increase. This increase is seen in people with cancers involving white blood cells, but it is particularly meaningful in people newly diagnosed with multiple myeloma. Multiple

WWW.BOOKBAZ.IR

KEY TERMS

Beta$_2$-microglobulin—A protein found on the surface of many cells, particularly white blood cells.

Chronic lymphocytic leukemia—A cancer of the blood cells characterized by large numbers of cancerous, mature white blood cells and enlarged lymph nodes.

Glomerular kidney disease—Disease of the kidney that affects the glomeruli, the part of the kidney that filters certain substances out of the blood.

Multiple myeloma—A malignancy (cancer) of a certain kind of white blood cell, called a plasma cell.

Non-Hodgkin's lymphoma—Cancer that originates in the lymphatic system and typically spreads throughout the body.

Tubular kidney disease—Disease of the kidney that affects the tubules, the part of the kidney that allows certain substances to be reabsorbed back into the blood.

myeloma is a malignancy (cancer) of a certain kind of white blood cell, called a plasma cell. At the time of diagnosis, the Beta$_2$-microglobulin levels reflect how advanced the disease is and the likely prognosis for that person.

When kidney disease is suspected, comparing blood and urine levels helps identify where the kidney is damaged. Beta$_2$-microglobulin normally is filtered out of the blood by the kidney's glomeruli (a round mass of capillary loops leading to each kidney tubule), only to be partially reabsorbed back into the blood when it reaches the kidney's tubules. In glomerular kidney disease, the glomeruli cannot filter it out of the blood, so levels increase in the blood and decrease in the urine. In tubular kidney disease, the tubules cannot reabsorb it back into the blood, so urine levels rise and blood levels fall. After a kidney transplant, increased blood levels may be an early sign of rejection.

Increased urinary levels are found in people with kidney damage caused by high exposure to the heavy metals cadmium and mercury. Periodic testing of workers exposed to these metals helps to detect beginning kidney damage.

Beta$_2$-microglobulin levels also rise during infection with some viruses, including cytomegalovirus and human **immunodeficiency** virus (HIV). Studies show that as HIV disease advances, beta$_2$-microglobulin levels rise.

Description

Testing methods vary, but most involve adding the person's serum—the yellow, liquid part of blood—or urine to one or more substances that bind to beta$_2$-microglobulin in the serum or urine. The amount of the substance(s) bound to beta$_2$-microglobulin is measured and the original amount of beta$_2$-microglobulin is determined.

The test is covered by insurance when medically necessary. Results are usually available the next day.

Preparation

The blood test requires 5 mL of blood. A healthcare worker ties a tourniquet on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

Urine may be a single collection or collected throughout a 24-hour time period. The urine should be refrigerated until it is brought to the laboratory and must not become acidic.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs on the puncture site relieve discomfort.

Results

- Serum: less than or equal to 2.7 g/mL
- Urine: less than 1 mg/24 hours or 0–160 g/L

Abnormal results

The meaning of an abnormal result varies with the clinical condition of the person tested. In a person with multiple myeloma, a higher level means a poorer prognosis than a lower level. In a person with kidney disease, an increased blood level means the problem is tubular, not glomerular. In a kidney transplant patient, an increase may be a sign of rejection, toxic amounts of antirejection medication, or a viral infection. An increased level in a worker exposed to cadmium or

mercury may signal beginning kidney damage, and in a person with HIV, advancing disease.

Bile duct cancer

Definition

Bile duct cancer, or cholangiocarcinoma, is a malignant tumor of the bile ducts within the liver (intrahepatic), or leading from the liver to the small intestine (extrahepatic). It is a rare tumor with poor outcome for most patients.

Description

Bile is a substance manufactured by the liver that aids in the digestion of food. Bile ducts are channels that carry the bile from the liver to the small intestine. Like the tributaries of a river, the small bile ducts in the liver converge into two large bile ducts called the left and right hepatic ducts. These exit the liver and join to form the common hepatic duct. The gallbladder, which concentrates and stores the bile, empties into the common hepatic duct to form the common bile duct. Finally, this large duct connects to the small intestine where the bile can help digest food. Collectively, this network of bile ducts is called the biliary tract.

Bile duct cancer originates from the cells that line the inner surface of the bile ducts. A tumor may arise anywhere along the biliary tract, either within or outside of the liver. Bile duct tumors are typically slow-growing tumors that spread by local invasion of neighboring structures and by way of lymphatic channels.

Bile duct cancer is an uncommon malignancy. In the United States, approximately one case arises per 100,000 people per year, but it is more common in Southeast Asia. It occurs in men only slightly more often than in women and it is most commonly diagnosed in people in their 50s and 60s. In fact, about 65% of patients with bile duct cancer are over age 65.

Causes and symptoms

A number of risk factors are associated with the development of bile duct cancer:

- Primary sclerosing cholangitis. This disease is characterized by extensive scarring of the biliary tract, sometimes associated with inflammatory bowel disease.
- Choledochal cysts. These are abnormal dilatations of the biliary tract that usually form during fetal development. There is evidence that these cysts may rarely arise during adulthood.
- Hepatolithiasis. This is the condition of stone formation within the liver (not including gallbladder stones).
- Liver flukes. Parasitic infection with certain worms is thought to be at least partially responsible for the higher prevalence of bile duct cancer in Southeast Asia.
- Thorotrast. This is a chemical that was previously injected intravenously during certain types of x rays. It is not in use anymore. Exposure to Thorotrast has been implicated in the development of cancer of the liver as well as the bile ducts.

Symptoms

Jaundice is the first symptom in 90% of patients. This occurs when the bile duct tumor causes an obstruction in the normal flow of bile from the liver to the small intestine. Bilirubin, a component of bile, builds up within the liver and is absorbed into the bloodstream in excess amounts. This can be detected in a blood test, but it can also manifest as yellowish discoloring of the skin and eyes. The bilirubin in the bloodstream also makes the urine appear dark. Additionally, the patient may experience generalized **itching** due to the deposition of bile components in the skin. Normally, a portion of the bile is excreted in stool; bile actually gives stool its brown color. But when the biliary tract is obstructed by tumor, the stools may appear pale.

Abdominal **pain**, **fatigue**, weight loss, and poor appetite are less common symptoms. Occasionally, if obstruction of the biliary tract causes the gallbladder to swell enormously yet without causing pain, the physician may be able to feel the gallbladder during a **physical examination**. Sometimes the biliary tract can become infected, but this is normally a rare consequence of invasive tests. Infection causes **fever**, chills, and pain in the right upper portion of the abdomen.

WWW.BOOKBAZ.IR

Diagnosis

Certain laboratory tests of the blood may aid in the diagnosis. The most important one is the test for elevated bilirubin levels in the bloodstream. Levels of alkaline phosphatase and CA 19-9 may also be elevated.

When symptoms, physical signs, and blood tests point toward an abnormality of the biliary tract, the next step involves radiographic exams. **Ultrasound**, computed tomography (CT scan), and **magnetic resonance imaging** (MRI) are noninvasive and rapid. In recent years, MRI has become the favored imaging choice for initial diagnosis of cholangiocarcinoma when the exam is available and affordable or covered by insurance. These tests can often detect the actual tumor as well as dilatation of the obstructed biliary tract. If these tests indicate the presence of a tumor, cholangiography is required. This procedure involves injecting dye into the biliary tract to obtain anatomic images of the bile ducts and the tumor. The specialist that performs this test can also insert small tubes, or stents, into a partially obstructed portion of the bile duct to prevent further obstruction by growth of the tumor. This is vitally important since it may be the only intervention that is possible in certain patients. Cholangiography is an invasive test that carries a small risk of infection of the biliary tract. The objective of these radiological tests is to determine the size and location of the tumor, as well as the extent of spread to nearby structures.

The treatment of bile duct tumors is usually not affected by the specific type of cancer cells that comprise the tumor. For this reason, some physicians forego biopsy of the tumor.

Treatment

The treatment is with surgical resection (removal) of the tumor and all involved structures. Unfortunately, sometimes the cancer has already spread too far when the diagnosis is made. Thus, in the treatment of bile duct cancer, the first question to answer is if the tumor may be safely resected by surgery with reasonable benefit to the patient. If the cancer involves certain blood vessels or has spread widely throughout the liver, resection may not be possible. Sometimes further invasive testing is required.

Angiography can determine if the blood vessels are involved. **Laparoscopy** is a surgical procedure that allows the surgeon to directly assess the tumor and nearby lymph nodes without making a large incision in the abdomen. Only about 45% of bile duct cancers are ultimately resectable.

If the tumor is resectable, and the patient is healthy enough to tolerate the operation, the specific type of surgery performed depends on the location of the tumor. For tumors within the liver or high up in the biliary tract, resection of part of the liver may be required. Tumors in the middle portion of the biliary tract can be removed alone. Tumors of the lower end of the biliary tract may require extensive resection of part of the pancreas, small intestine, and stomach to ensure complete resection.

Unfortunately, sometimes the cancer appears resectable by all the radiological and invasive tests, but is found to be unresectable during surgery. In this scenario, a bypass operation can relieve the biliary tract obstruction, but does not remove the tumor itself. This does not produce a cure but it can offer a better quality of life for the patient.

Prognosis

Prognosis depends on the stage and resectability of the tumor. If the patient cannot undergo surgical resection, the survival rate is commonly less than one year. If the tumor is resected, the survival rate improves, with 20% of these patients surviving past five years.

Clinical trials

Studies of new treatments in patients are known as clinical trials. These trials seek to compare the standard method of care with a new method, or the trials may be trying to establish whether one treatment is more beneficial for certain patients than others. Sometimes, a new treatment that is not being offered on a wide scale may be available to patients participating in clinical trials, but participating in the trials may involve some risk. To learn more about clinical trials, patients can call the National Cancer Institute (NCI) at 1-800-4-CANCER or visit the NCI website for patients at www.cancertrials.nci.nih.gov.

Prevention

Other than the avoidance of infections caused by liver flukes, there are no known preventions for this cancer.

Biliary atresia

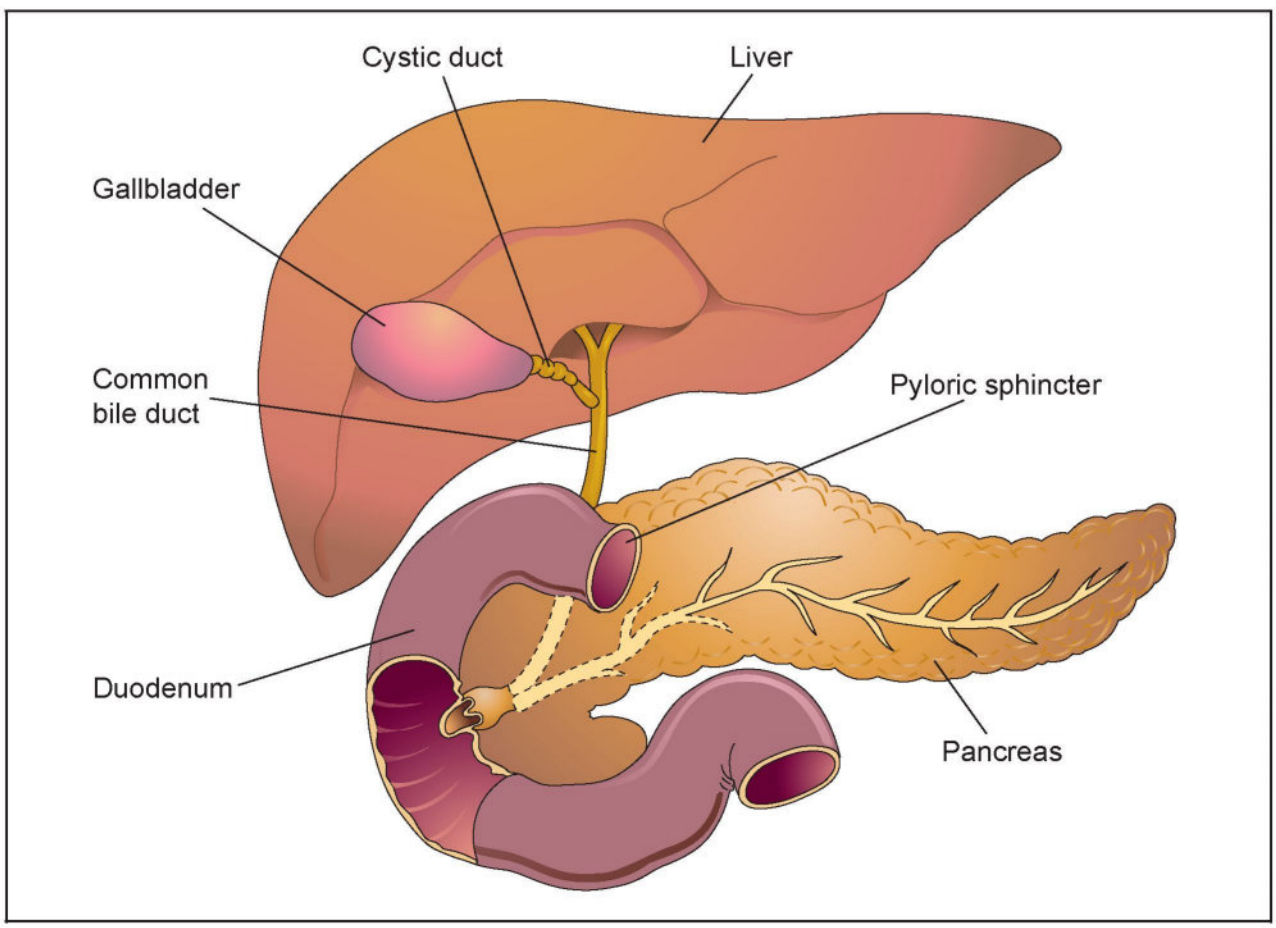
Definition

Biliary atresia is the failure of a fetus to develop an adequate pathway for bile to drain from the liver to the intestine.

Description

Biliary atresia is the most common lethal **liver disease** in children, occurring once every 10,000–15,000 live births. Half of all liver transplants are done for this reason.

The normal anatomy of the bile system begins within the liver, where thousands of tiny bile ducts collect bile from liver cells. These ducts merge into larger and larger channels, like streams flowing into rivers, until they all pour into a single duct that empties into the duodenum (first part of the small intestine). Between the liver and the duodenum this duct



Biliary atresia is a congenital condition in which the pathway for bile to drain from the liver to the intestine is undeveloped. It is the most common lethal liver disease in children. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

WWW.BOOKBAZ.IR

has a side channel connected to the gall bladder. The gall bladder stores bile and concentrates it, removing much of its water content. Then, when a meal hits the stomach, the gall bladder contracts and empties its contents.

Bile is a mixture of waste chemicals that the liver removes from the circulation and excretes through the biliary system into the intestine. On its way out, bile assists in the digestion of certain nutrients. If bile cannot get out because the channels are absent or blocked, it backs up into the liver and eventually into the rest of the body. The major pigment in bile is a chemical called bilirubin, which is yellow. Bilirubin is a breakdown product of hemoglobin (the red chemical in blood that carries oxygen). If the body accumulates an excess of bilirubin, it turns yellow (jaundiced). Bile also turns the stool brown. Without it, stools are the color of clay.

Causes and symptoms

It is possible that a viral infection is responsible for this disease, but evidence is not yet convincing. The cause remains unknown.

The affected infant will appear normal at birth and during the newborn period. After two weeks the normal **jaundice** of the newborn will not disappear, and the stools will probably be clay colored. At this point, the condition will come to the attention of a physician. If not, the child's abdomen will begin to swell, and the infant will get progressively more ill. Nearly all untreated children will die of liver failure within two years.

Diagnosis

The persistence of jaundice beyond the second week in a newborn with clay-colored stools is a sure sign of obstruction to the flow of bile. An immediate evaluation that includes blood tests and imaging of the biliary system will confirm the diagnosis.

Treatment

Surgery is the only treatment. Somehow the surgeon must create an adequate pathway for bile to escape the liver into the intestine. The altered anatomy of the biliary system is different in every case, calling upon the surgeon's skill and experience to select and execute the most effective among several options. If the obstruction is only between the gall bladder and the intestine, it is possible to attach a piece of intestine directly to the gall bladder. More likely, the upper biliary system will also be inadequate, and the surgeon will attach a piece of intestine directly to the liver—the Kasai procedure. In its wisdom, the body will discover that the tiny bile ducts in that part of the liver are discharging their bile directly into the intestine. Bile will begin to flow in that direction, and the channels will gradually enlarge. Survival rates for the Kasai procedure are commonly 50% at five years and 15% at 10 years. Persistent disease in the liver gradually destroys the organ.

Prognosis

Before liver transplants became available, even prompt and effective surgery did not cure the whole problem. Biliary drainage can usually be established, but the patients still have a defective biliary system that develops progressive disease and commonly leads to an early death. Transplantation now achieves up to 90% one-year survival rates and promises to prevent the chronic disease that used to accompany earlier procedures.

Prevention

The specific cause of this birth defect is unknown, so all that women can do is to practice the many general preventive measures, even before they conceive.

Binge drinking

Definition

Binge drinking is the rapid consumption of alcohol with the goal of intoxication. In the past, binge drinking was usually considered to be heavy, out-of-control drinking, usually alone, for periods of up to several days. Binge drinking is now more often defined by the quantity of alcohol consumed on a single occasion. The National Advisory Council of the National Institute on Alcohol Abuse and **Alcoholism** (NIAAA) defines binge drinking as reaching a blood alcohol concentration (BAC) of at least 0.08 grams per deciliter, which generally corresponds to five drinks within

about two hours for adult males and four drinks for adult females.

Demographics

Binge drinking is common in most parts of the world, and alcohol consumption, including binge drinking, is a major cause of death. Every year, more than 33 million adult Americans binge drink. According to national surveys released in 2010 and reported by the U.S. Centers for Disease Control and Prevention, 75% of the alcohol consumed by U.S. adults is consumed by binge drinking. Among Americans who drink, almost one in three adults and two out of three high school students binge drink. Among American adults who drink to excess, approximately 92% report binge drinking at least once in a 30-day period. Binge drinking is more prevalent in males (21% vs. 10% of females). Among non-Hispanic whites, 16% binge drink, compared with 10% of non-Hispanic blacks. Binge drinking varies greatly from state to state, with estimates of binge drinking by adults ranging from 6.8% in Tennessee to 23.9% in Wisconsin. Binge drinkers are 14 times more likely than other drinkers to drive while alcohol impaired.

Although 70% of binge-drinking episodes in the United States involve adults aged 26 and older, binge drinking by high school and college students is of particular concern. Binge drinking accounts for approximately 90% of all alcohol consumed by Americans under the age of 21, and 51% of 18–20-year-olds who drink alcohol binge drink, the highest proportion for any age group.

Although binge drinking among young people appears to be increasing in many countries, binge drinking by U.S. college students has remained stable over time. Rates vary with the individual school, from 1% to more than 70% of students. Overall, more than 40% of U.S. college students of all ages report binge drinking at least once during an average two-week period. Every year, an estimated 30,000 American college students require medical treatment for alcohol overdose. Among students who drive at least once a week, 13% report driving after having at least five drinks, and within all age groups, persons who binge drink are 14 times more likely to drive while under the influence.

Description

Binge drinking is generally recognized as a harmful—and potentially life-threatening—practice, but there is no universally accepted definition of what constitutes binge drinking. Some U.S. researchers prefer the phrase "episodic heavy drinking," referring to at least five consecutive drinks for men and at least four for women on at least one occasion in a two-week period. Three or more such episodes within two weeks constitute heavy binge drinking. In many European countries, however, binge drinking is defined by significantly more than four or five drinks. There is also considerable variation in the definition of a standard drink. Furthermore, alcohol is metabolized at different rates. A person's BAC is affected by body weight, the duration of time in which alcohol is consumed, and concurrent food intake. To account for these factors, the NIAAA has redefined binge drinking as a pattern of consumption that brings the BAC to 0.08 gram percent or above. However, all definitions of binge drinking include drinking to the point of intoxication.

One standard drink is generally defined as:

- 12 fluid ounces (fl oz) of regular beer
- 8–9 fl oz of malt liquor
- 5 fl oz of table wine
- 3–4 fl oz of fortified wine, such as sherry or port
- 2–3 fl oz of cordial, liqueur, or aperitif
- 1.5 fl oz (one jigger or shot) of brandy or 80-proof spirits (hard liquor)

The acceptability of binge drinking varies in different cultures. In some societies, binge drinking and intoxication are considered normal. In most cultures that tolerate drinking, binge drinking is more acceptable for males than for females and may even be considered a male rite of passage. Binge drinking may also be acceptable on certain occasions, such as wedding celebrations, wakes, or sports tournaments.

Binge drinking is associated with numerous social problems. It increases the likelihood of high-risk behaviors, such as driving under the influence; engaging in unplanned, unsafe, unprotected, or nonconsensual sex; accidents or injuries due to loss of physical coordination; and aggression or violence. People that binge drink are more likely to miss school or work and to perform less productively because of hangovers. They may engage in inappropriate interpersonal behaviors that negatively affect their relationships. Schools with high rates of binge drinking have higher rates of property damage and verbal, physical, and sexual violence.

Binge drinking is associated with a variety of adverse health effects, including cardiovascular problems such as **atrial fibrillation**. Binge drinking by pregnant women can directly harm their unborn babies and cause **fetal alcohol syndrome** or another fetal alcohol spectrum disorder. Binge drinking is also

WWW.BOOKBAZ.IR

associated with **liver disease**, neurological damage, **sexual dysfunction**, and poor control of diabetes. Finally, binge drinking can cause potentially fatal alcohol **poisoning**.

Risk factors

Risk factors for binge drinking include **stress**, **sexual abuse**, and mental illness. Additional risk factors for college students include having engaged in binge drinking in high school and residing in a sorority or fraternity. Low-priced, easily available alcohol is strongly correlated with binge drinking by college students. Binge drinking rates among college students correlate with those of adults living in the same state—36% in the ten states with the lowest rates of adult binge drinking compared with 53% in the ten highest adult–binge drinking states.

Causes and symptoms

The causes of binge drinking can be psychological or social. Many people binge drink to escape stress or personal problems. Other binge drinkers, especially young people, report that they engage in the practice because of peer pressure, for social status, or to fit in with a drinking culture. Bars, liquor stores, and advertising promote drinking as an attractive activity.

The rise in popularity of inexpensive alcoholic **energy drinks**, which contain **caffeine** and other stimulants in addition to high alcohol levels, led to a frightening increase in binge drinking in the late 2000s, especially among college students. These products appear to be designed to support binge drinking, as the stimulants enable drinkers to stay awake and consume more alcohol, rather than passing out. Numerous hospitalizations and several deaths led some colleges and states to ban the drinks, and because the safety of such supplements in combination with alcohol had not been approved by the U.S. Food and Drug Administration (FDA), manufacturers were required by the FDA to remove caffeine from the beverages.

Although binge drinkers are not necessarily alcohol dependent, three out of five frequent binge drinkers may meet the criteria for alcohol abuse and one in five may be alcohol dependent. Some studies indicate that people who have three or more binge-drinking episodes within a two-week period display some symptoms of alcoholism.

Alcohol poisoning can be a potentially life-threatening consequence of binge drinking. Alcohol poisoning affects involuntary reflexes, including breathing and the gag reflex. An impaired gag reflex can cause drinkers to choke on their own vomit. Other signs of alcohol poisoning include:

- extreme confusion
- seizures
- unconsciousness
- slow or irregular breathing
- lowered body temperature
- pale or bluish skin

KEY TERMS

Alcoholic energy drink—Caffeinated alcoholic beverages; malt liquors which, in addition to high alcohol content, have added caffeine and sometimes other stimulants.

Alcohol poisoning—A potentially life-threatening condition caused by consuming large amounts of alcohol over a short period, negatively affecting heart rate, breathing, and the gag reflex.

Atrial fibrillation—A condition in which the upper chamber of the heart quivers instead of pumping in an organized way.

Blood alcohol concentration or content (BAC)—A measure of the amount of alcohol in the body; in most states, alcohol intoxication is defined as a BAC of at least 0.08 grams per deciliter of blood.

Cognitive-behavioral therapy (CBT)—A type of psychotherapy in which people learn to recognize and change negative and self-defeating patterns of thinking and behavior.

Fetal alcohol spectrum disorders—A range of birth defects, including intellectual disability, poor growth, nervous system dysfunctions, and malformations, that result from heavy maternal alcohol consumption during pregnancy.

Tolerance—The body's adjustment to a drug such as alcohol, requiring increasingly higher quantities to produce the same effects.

Withdrawal—The unpleasant, sometimes life-threatening, physiological changes that can occur due to the discontinuation of alcohol or other drugs after prolonged regular use.

Diagnosis

Examination

Although people usually recover from binge drinking by "sleeping it off," alcohol poisoning is a

medical emergency that requires immediate attention. The physician will check for signs and symptoms of alcohol poisoning. It is important that medical personnel be informed as to the amount and type of alcohol consumed over a specific period of time.

Tests

Blood tests are used to determine blood alcohol levels and other signs of alcohol toxicity, such as low blood sugar. A urine test may help to confirm a diagnosis of alcohol poisoning.

Treatment

The most important treatment for binge drinking is to stop drinking. Binge drinkers should never be allowed to drive. If alcohol poisoning is suspected, it is important to stay with the person and try to keep them conscious until medical help arrives. If they are **vomiting**, they should be kept in a sitting position if possible, or, if lying down, have their head turned to one side to prevent **choking**. Patients with alcohol poisoning must be carefully monitored to prevent breathing and gagging problems. **Oxygen therapy** may be required, as well as intravenous fluids to prevent **dehydration**.

Traditional

Patients who are physically dependent on alcohol may require medical treatment for managing symptoms of alcohol withdrawal. Counseling may be required to address the underlying reasons for alcohol abuse. Groups such as Alcoholics Anonymous (AA) have a proven track record of helping people with drinking problems. Alcoholism is also treated with **cognitive-behavioral therapy** (CBT) or interactional group **psychotherapy** based on a 12-step program. Severe cases may require hospitalization or treatment in a substance-abuse **rehabilitation** facility.

Drugs

Anxiolytic drugs are sometimes prescribed to control **anxiety** symptoms that accompany alcohol withdrawal. The FDA has approved three medications for the treatment of alcoholism:

- disulfiram (Antabuse) causes illness if alcohol is consumed
- naltrexone (Depade, ReVia) acts on the brain to reduce the craving for alcohol
- acamprosate (Canpral) reduces withdrawal symptoms

Prognosis

Binge drinking is particularly dangerous for young people whose brains are still developing. Young people are more likely than adults to engage in risky behaviors when binge drinking, leading to automobile accidents, violence, sexually transmitted diseases, and unplanned pregnancies. Binge drinking disrupts sleep patterns, making it harder to concentrate in school, and binge drinkers are more likely to drop out of school. Studies have shown that teens who binge drink throughout high school are more likely to be overweight and have high blood pressure by the age of 24. Binge drinking can cause people to become angry or moody and socially isolated. Frequent binge drinking can induce tolerance, so that more alcohol is required to achieve a particular level of intoxication. Over time, binge drinking can cause liver disease, **heart disease**, and other chronic conditions, as well as **stroke** and certain cancers. Binge drinking by pregnant women can cause fetal alcohol spectrum disorders and other harm to their babies. Severe alcohol poisoning can lead to irreversible brain damage or death. Finally, binge drinking may be a precursor to alcohol dependence.

Prevention

Evidence demonstrates that parental influence and family values are very powerful determinants of drinking behavior. School- and community-based educational programs, starting in middle school if not before, teach alcohol awareness and stress the dangers of binge drinking. Many colleges and universities have alcohol awareness and prevention programs, beginning with freshman orientation. Peer-to-peer counseling and interactive programs can be particularly effective. Alcohol awareness programs can also be directed toward workplaces and promoted in the mainstream media. Healthcare providers and social service workers should educate their patients and clients.

Social norms approaches teach that activities such as binge drinking are not socially acceptable. Social norming has been shown to be especially effective in reducing binge drinking among young people. For example, many young people believe that binge drinking is much more prevalent than it actually is, and correcting this misconception can discourage the practice.

One study found that in seven states that had at least four laws targeting high-volume alcohol sales, campus binge-drinking rates were lower—33% compared to 48% in states without such laws. States with other alcohol-control policies also had lower rates of college binge drinking. Other interventions that have been shown to help prevent binge drinking in college students include:

WWW.BOOKBAZ.IR

- increasing the cost of alcoholic beverages through taxation
- limiting the number of retail alcohol outlets within a given area
- consistently enforcing laws against underage drinking and drunk driving
- screening and counseling students for alcohol abuse

Bars and restaurants can also play a role in reducing binge drinking. Atmosphere, such as lighting and music, can affect how much and how fast patrons drink. Serving alcohol at a slower rate, offering food and nonalcoholic drinks, and especially refusing to serve intoxicated customers and preventing them from driving are business practices that help discourage binge drinking.

Margaret Alic, PhD

Binge eating disorder

Definition

Binge eating disorder (BED) is a serious eating disorder characterized by frequent consumption of a large amount of food over a limited period of time, such as one or two hours. BED is also known as compulsive overeating.

Demographics

Binge eating disorder is the most commonly diagnosed eating disorder, affecting 3.5% of women and 2% of men at some point in their adult lives. Although it often begins in late adolescence or early twenties, BED is also common during middle age. As many as one-half of people attending weight-loss clinics are binge eaters. Although BED affects blacks and whites equally, there has been little research on binge eating by other racial or ethnic groups.

Data from a 2011 study conducted by the National Institutes of Mental Health showed that the lifetime prevalence of binge eating disorder in teens is 1.6% (approximately 300,000 teens). The study was based on interviews with more than 10,000 adolescents aged 13 to 18 years. The study data also showed that rates of binge eating disorder, as well as bulimia, have approximately doubled since 1990, while the rates of anorexia have remained fairly stable. More girls were affected by binge eating disorder than boys, and approximately 15% of any teens with binge eating disorder had attempted **suicide**.

Description

Although most people overeat on occasion, BED is a pattern of frequently recurring abnormal overeating, which is different from continuous snacking and often occurs in the absence of hunger. Although the duration of each binge may vary significantly, binge eating is characterized by the inability to stop eating during each episode and a feeling of being out of control. A binge typically ends only when all of the desirable binge foods have been consumed or when the person feels too full to continue. Binge eaters generally eat very fast and alone—usually out of embarrassment—and suffer strong negative feelings such as guilt, shame, or depression following the binge.

Many eating disorder specialists define BED as overeating that occurs at least twice a week for at least three months and that has a negative effect on an individual's health, relationships, and/or daily activities. However, BED is a relatively new area of research, and many aspects of the disorder remain unclear.

In the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*), the American Psychiatric Association (APA) defines the better known—but less common—eating disorders, **anorexia nervosa** and **bulimia nervosa**, as psychiatric disorders with formal diagnostic criteria. BED is also included as a specific disorder in the fifth edition of the *DSM*, *DSM-5* (2013). This is important because the classification can affect both recommended therapies and health insurance coverage for treatment. However, the proposal has proved controversial.

The proposed diagnostic criteria state that individuals must experience binge eating episodes at least once a week for three months to be diagnosed with binge eating disorder.

Some experts believe that binge eating should be classified as an obesity-related behavior. However, not all binge eaters are obese and not all obese people are binge eaters. Furthermore, binge eaters are far more likely to report significant mood problems, especially depression, and greater dissatisfaction with their weight and shape, as compared to persons with **obesity**.

Other experts believe that binge eating is a subtype of bulimia. Bulimia is characterized by episodes of binge eating followed by self-induced purging through **vomiting**; abuse of **laxatives**, **diuretics**, or **enemas**; **fasting**; or compulsive **exercise**. Although persons with BED often attempt to diet between binges, they do not purge extra calories. They also do not exhibit anorexic or self-starving behaviors, which may occur in persons with bulimia.

Risk factors

Risk factors for binge eating are similar to risk factors for other **eating disorders**. These include:

- a family history of eating disorders
- frequent dieting, especially rigorous diets or frequently gaining and losing large amounts of weight (weight cycling)
- preoccupation with weight and body image
- impulsiveness or poor impulse control
- low self-esteem and negative self-talk
- difficulty expressing feelings appropriately and managing anger
- a history of sexual abuse
- depression, which can be both a risk factor for binge eating and a result of binge eating

Causes and symptoms

Like other eating disorders, BED has multiple causes. Some people appear to be genetically predisposed to binge eating. Researchers believe that this may be related to abnormalities in brain neurotransmitters that help regulate appetite. Binge-eating episodes may occur in response to strong negative emotions, such as depression or **anxiety**, or to less defined feelings of distress or tension. People who binge eat are far more likely than others to describe themselves as experiencing personal and work problems and as being hypersensitive to the opinions of others. Like with bulimia, persons with BED are more likely than others to be diagnosed with major depression, substance-related disorders, and **personality disorders**. Binge eating is often triggered by stress—sometimes the **stress** is caused by very restrictive **diets**, but often the stress is caused by social and cultural factors, such as family conflicts or dysfunctional

WWW.BOOKBAZ.IR

relationships. Pressure felt by cultural and media messages that promote being thin as desirable can also result in binge eating, which is used as a coping mechanism. Some patients report that their binges are related to the ingestion of certain "trigger foods," usually carbohydrates.

Whatever the cause, bingeing appears to temporarily alleviate uncomfortable or painful feelings. While bingeing, patients typically describe themselves as "numb" or "spaced out." Their relief is short-lived, leading to repeated bingeing. The out-of-control eating is a frightening experience for most people, and they usually feel embarrassed and ashamed about their bingeing. In the aftermath of a binge, many people experience overwhelming feelings of guilt, self-disgust, anxiety, and depression. They vow never to binge again but are unable to prevent it.

Symptoms of binge eating can be difficult to detect. The eating often occurs in private, and the eater tends to be secretive about food. Specific symptoms of binge eating include:

- feeling out of control and unable to stop eating
- continuing to eat despite feeling full or even painfully uncomfortable
- eating abnormally large amounts of food at one sitting, sometimes as many as 3,000–10,000 calories in a short period
- eating abnormally fast
- eating alone or in secret
- hoarding food and hiding empty food containers
- constant dieting without weight loss
- obsessive concern with weight
- depression
- anxiety
- substance abuse

Diagnosis

Diagnosis requires examination, tests, and compiling relevant personal information.

Examination

Diagnosis should include a **physical examination** and medical history, although binge eating disorder is often diagnosed and treated by a psychiatrist or psychologist. Diagnosis can be difficult. Binge eaters often go to extremes to hide how much they eat. They may, for example, buy snack food at the grocery store and eat it in the car before they get home or buy food in secret and hoard it. Although diagnosis usually begins with a personal and family history, including eating habits and exercise, binge eaters may lie about their eating.

Tests

Physicians usually order standard laboratory tests, including a **complete blood count** (CBC), **urinalysis**, and blood tests to check levels of **cholesterol**, **triglycerides**, and electrolytes. Additional tests, such as thyroid function, may be ordered to rule out

KEY TERMS

Anorexia nervosa—A serious eating disorder that primarily affects young women in their teens and early twenties and is characterized by a pathological fear of gaining weight. Anorexia causes disturbed eating behavior and can lead to severe weight loss and malnutrition.

Bulimia nervosa—A serious eating disorder that primarily affects young women and is characterized by compulsive overeating followed by purging, usually self-induced vomiting or the use of laxatives or diuretics.

Cognitive-behavioral therapy (CBT)—A type of psychotherapy in which people learn to recognize and change negative and self-defeating patterns of thinking and behavior.

Electrolytes—Ions, such as sodium, potassium, calcium, magnesium, chloride, phosphate, bicarbonate, and sulfate, that are dissolved in bodily fluids such as blood and regulate or affect most metabolic processes.

Neurotransmitters—Chemicals that carry impulses between nerve cells (neurons), including acetylcholine, dopamine, serotonin, and norepinephrine.

Selective serotonin reuptake inhibitors (SSRIs)—A class of antidepressants that works by blocking the reabsorption of serotonin by brain cells, raising the level of the chemical in the brain.

Serotonin—5-Hydroxytryptamine; a neurotransmitter present throughout the body, especially in the brain. Inadequate amounts of serotonin have been implicated in numerous disorders, including depression and obsessive-compulsive disorder.

Triglycerides—A type of fat in the blood. High levels of triglycerides can increase the risk of coronary artery disease.

Weight cycling—Repeatedly gaining and losing weight.

other disorders. If the patient is obese, tests may be performed for obesity-related conditions, such as diabetes, cardiovascular disease, and **sleep apnea**.

Procedures

The assessment process may include a questionnaire, such as the Eating Disorder Examination Questionnaire. There are several clinical inventories or scales that are used to assess depressive symptoms, including the Hamilton Depression Scale (HAM-D) and the Beck Depression Inventory (BDI). These tests are usually administered in an office setting.

Treatment

There are various approaches in treating BED; however, for the best results, patients must want to stop binge eating.

Traditional

BED is usually treated most effectively by a combination of **psychotherapy** and **group therapy**. However, physicians are more likely to concentrate on weight-control issues, using drugs, diet, and **nutrition** counseling to reduce the health risks of obesity-related diseases. Although nutrition counseling and meal planning may help control weight, they do not address the impulse to binge eat. Psychologists are more likely to treat behavior and thought patterns that cause abnormal eating, since obesity may be easier to treat once bingeing behavior is controlled.

Several types of psychotherapy may be effective for treating BED. **Cognitive-behavioral therapy** (CBT) is a relatively short-term therapy designed to confront and change thoughts and feelings about one's body and behaviors toward food. It does not address the origins of those thoughts and feelings, but rather explores self-control strategies and the development of skills for coping with emotional distress. Interpersonal therapy is short-term therapy to help identify and resolve specific relationship issues and problems and has been shown to be successful in the treatment of BED. Dialectical behavior therapy (DBT) utilizes structured private and group sessions for reducing behaviors that interfere with quality of life, finding alternate solutions to current problem situations, and learning to regulate emotions. **Family therapy** is helpful for treating children who binge eat. It teaches strategies for reducing conflict, disorder, and stress that can trigger binge eating.

Drugs

There are no drugs specifically approved by the U.S. Food and Drug Administration (FDA) for treating binge eating. However, the FDA has approved antidepressants called **selective serotonin reuptake inhibitors** (SSRIs), such as fluoxetine (Prozac) and sertraline (Zoloft), for the treatment of bulimia, which involves binge-eating behavior. These medications increase serotonin levels in the brain and are thought to affect the body's sense of fullness. SSRIs are often prescribed for BED, regardless of whether there are signs of depression. Tricyclic antidepressants (TCAs) and appetitive suppressants may be prescribed for BED, but their use is rare. The anticonvulsant topiramate (Topamax), which is normally used to control seizures, has been found to reduce binge-eating episodes, but this drug can have serious side effects.

Alternatives

Alternative treatments for binge eating often focus on curbing concurrent depression. Herbal remedies that may ease symptoms of depression include 5-HTP, DHEA, saffron, and St. John's wort; kava-kava root may reduce symptoms of anxiety. Relaxation exercises and techniques that may help reduce binge-eating episodes triggered by stress or depression include **music therapy**, **yoga**, and other forms of relaxation.

Home remedies

Although weight-loss programs are helpful for some people with BED, they generally are not recommended until after BED treatment, since low-calorie diets can trigger binge eating. Weight-loss programs generally do not address binge-eating triggers to the same extent as psychotherapy. Weight loss should be medically supervised.

Self-help programs, including books and manuals, videos, and support groups, can be helpful for treating BED. A 2010 study of patients with at least one binge-eating episode per week found that 64% of patients who attended eight therapy sessions utilizing a six-step self-help program were binge free after one year. This compared with 45% of patients who were given only basic healthy eating information and informed of available services.

Self-help programs are cost-effective as well. In another 2010 study of 123 patients with binge eating disorder, a guided self-help program was significantly more cost effective than simply providing patients with options for treatment. The cost to society in terms of binge-free days and workplace productivity was significantly reduced in the intervention group, with a savings of more than $26,000 per quality of life year.

Home remedies for binge eating include eating breakfast, avoiding diets, getting appropriate essential

WWW.BOOKBAZ.IR

nutrients, and keeping less food in the home. Binge eaters are also advised to exercise and seek support from friends and family members.

Prognosis

Overall rates of recovery are higher for BED than for bulimia. Some people find that simply the act of seeking help or taking a placebo improves their control over binge eating. This is one reason why some medical professionals do not accept binge eating as a genuine disorder. In any case, binge-eating relapses are common in response to stressful life events.

Prevention

Binge eating is difficult to prevent, since its causes are unclear, and it can be difficult to detect. Prevention strategies include:

- eating small meals every three or four hours to avoid hunger
- tracking food intake
- avoiding eating alone
- avoiding using food for comfort in times of stress
- monitoring negative self-talk and practicing positive self-talk
- spending time doing something enjoyable every day
- staying busy without becoming frantic or stressed
- being aware of situations that invite bingeing and looking for ways to avoid or defuse such situations
- avoiding extreme diets
- teaching children to have healthy attitudes toward their weight, appearance, and diet
- avoiding comparisons or teasing about body size and shape
- loving and accepting family members for who they are
- being alert for signs of low self-esteem, anxiety, depression, and drug or alcohol abuse, and seeking help if signs appear

Biochemistry

Definition

Biochemistry is the study of the chemical principles and processes of life. It includes the structures and activities of the molecules and cells that make up living organisms. Thus, biochemistry includes the study of heredity, development, growth, maintenance, reproduction, and death of cells and organisms in both normal and diseased physiologic states.

Description

Biochemistry is the study of: the molecules of life, such as proteins, carbohydrates, lipids or fats, and nucleic acids; their synthesis, degradation, and functions in metabolism; heredity and reproduction; and growth and maintenance of life. With the sequencing of human genomes and advances in bioinformatics, it has become apparent that the biochemistry of each individual has its own unique characteristics.

In the latter decades of the 20th century, as the sciences of biochemistry and molecular biology were both advancing at breathtaking speeds, the two fields began to merge. The distinctions between biochemistry and molecular biology have faded to the point that they are often considered a single scientific discipline. Biochemical science overlaps, not just with biology, but also with organic and inorganic chemistry, biophysics, engineering, and computer science. Thus, biochemistry is usually performed by teams of scientists, often trained in different disciplines. To a large extent, biochemistry research in the United States is funded by the federal government, especially the National Science Foundation (NSF) and the National Institutes of Health (NIH).

Biochemistry involves both basic research to expand human knowledge and applied research aimed at solving particular problems. Although much of the science of biochemistry focuses on human **physiology** and medical science, biochemistry is concerned with all living organisms. Biochemists genetically engineer crops to generate resistance to drought, disease, insects, pesticides, and herbicides; to improve crop yields; and to reduce the resources required to raise food crops. Biochemistry is also involved in the development of alternative fuels, such as biofuels from plants, and in developing improved methods for environmental protection and cleanup.

Biochemistry utilizes a wide variety of scientific methods and instrumentation, including:

- protein sequencing and synthesis
- spectroscopy
- electrophoresis
- mass spectrometry
- radiochemistry
- lasers
- immunochemistry
- electron and other types of microscopy and imaging techniques
- cell culturing
- cell separation
- recombinant DNA and molecular biology technologies, include DNA cloning, sequencing, and mutagenesis
- genome sequencing and bioinformatics
- computer modeling

Origins

Modern biochemistry evolved out of 19th-century physiological chemistry, which was concerned with subjects such as the chemistry of digestion and bodily fluids. Freiderich Wöhler synthesized urea in 1828, demonstrating for the first time that a biological molecule could be produced outside of a living organism. Claude Bernard (1813–1878) is usually considered the founder of biochemistry, because he introduced the scientific method into medical studies. German chemist Carl Neuber is generally credited with coining the term

WWW.BOOKBAZ.IR

"biochemistry" in 1903, but the term may have been used as early as 1882.

Although humans have used enzymes in food processing for thousands of years, it was not until the 1830s, with the **isolation** of amylase (an enzyme that breaks down starch to sugars), that scientists began to examine the ways in which chemical reactions occur in living organisms. Emil Fischer proposed that a substrate—the molecule acted upon by an enzyme—fits into its enzyme like a key in a lock. By 1913, Leonor Michaelis and Maud Menten had derived the equations that describe enzyme activities, and in 1926, James Sumner crystallized urease, demonstrating for the first time that enzymes were proteins. Fred Sanger determined the first amino acid sequence of a protein in 1955 and the first amino acid sequence of an enzyme followed in 1959.

The crystallization of enzymes and other proteins enabled scientists to determine the structures of biological molecules by x-ray crystallography, and biochemists could begin relating protein structure to protein function. Rosalind Franklin's x-ray crystallography of deoxyribonucleic acid (DNA) enabled James Watson and Francis Crick to elucidate the structure of DNA in 1953, which, in turn, explained how DNA replicates itself when a cell divides, faithfully passing on its genetic information to its descendants. By the 1960s, the genetic code had been cracked: A specific order of three bases in DNA codes for each amino acid in a protein. The first genomic sequence—that of a virus that infects bacteria—was completed by Fred Sanger in 1977. Within less than three decades, the complete sequences of the human genome and many other organisms had been determined.

During first half of the 20th century, biochemists were uncovering the structures and functions of other important biological molecules—carbohydrates, lipids, hormones, and the components of the immune system. By the 1930s, adenosine triphosphate (ATP) was recognized as the energy currency of cells, linking oxygen uptake with phosphorylation and cellular respiration. The major metabolic pathways—including the urea cycle, glycolysis, the Krebs or citric acid cycle, and the pathway for fatty acid oxidation—were elucidated. By the 1950s, scientists had also obtained a detailed understanding of the biochemistry of photosynthesis.

Proteins

Together, all of the proteins present in a cell or organism make up its proteome, whereas all of the genes in a cell or organism make up its genome.

Proteins include:

- enzymes that catalyze or promote chemical reactions, such as amylase, urease, and alcohol dehydrogenase that detoxifies alcohol and converts it to sugars. Often, enzymes come together in multi-enzyme complexes, forming molecular machines that carry out coordinated biochemical functions. The mechanisms of enzyme function—enzyme kinetics and inhibition—is a very important aspect of biochemistry.
- structural proteins, such as collagen, which provides structure and support to skin, tendons, bones, and other tissues and organs, and fribrin, which forms scabs over wounds
- carrier proteins that transport nutrients through the blood to all the cells of the body, including hemoglobin that carries oxygen
- actin, which helps muscles contract
- channels and receptors, which enable chemical signals and small molecules to enter and exit cells, including the cells of the brain and nervous system
- small proteins such as hormones, which are chemical messengers that carry signals from the brain and other organs to regulate functions throughout the body, including insulin, which regulates blood sugar, and growth hormone, which regulates growth and development

A major focus of biochemistry is the study of the how the structures of proteins determine their functions. Function depends, not only on the amino acid sequence of a protein, but also on its correct folding in three-dimensional space and various chemical modifications to the protein.

Metabolism

Biochemistry includes nutritional science and studies of the digestion, absorption, and specific functions of both macronutrients—carbohydrates, fats, and proteins—and micronutrients including **vitamins** and **minerals**. Biochemists study the metabolic pathways by which enzymes convert carbohydrates, lipids, and proteins into energy for cells and organisms, as well as the pathways by which amino acids, proteins, and nucleic acids are synthesized and degraded. Bioenergetics concerns the pathways for the transformation of molecules into energy, which occurs in the mitochondria of cells through oxidative metabolism.

Molecular and cell biology

Biochemistry encompasses the science of genetics at the molecular level. It includes studies of the ways in which DNA codes for proteins, replicates or reproduces itself, is transmitted to daughter cells during cell division, recombines and repairs itself, and undergoes the mutations that drive evolutionary change. By manipulating DNA, biochemists and molecular biologists can produce proteins in large quantities. They

KEY TERMS

Adenosine triphosphate (ATP)—A nucleotide with three phosphate groups that supplies cellular energy by undergoing enzymatic hydrolysis to adenosine diphosphate (ADP) and adenosine monophosphate (AMP).

Amino acids—Small molecules that form the chains or primary sequences of proteins and are coded for by the sequences of nucleotides in DNA and RNA; some amino acids are synthesized by the human body and others must be obtained from food.

Antibodies—Specific proteins produced by the immune system in response to specific foreign proteins or particles called antigens.

Bioinformatics—The use of computer science for collecting, classifying, and analyzing biochemical and genetic information.

Carbohydrates—Sugars, starches, celluloses, and gums that are a major source of energy from foods.

Enzyme—A protein that promotes a biochemical reaction.

Gene—A specific sequence of nucleotides in DNA or RNA that specifies a particular protein or portion of a protein or that regulates the function of other genes.

Glycolysis—The breakdown of glucose or glycogen to pyruvate to supply cellular energy.

Hormone—A substance, such as a protein, that is produced in one part of the body and travels through the bloodstream to affect another part of the body.

Insulin—A protein hormone synthesized in the pancreas that is required for the metabolism of carbohydrates, lipids, and proteins and that regulates blood sugar levels.

Lipids—Fats; organic compounds that are stored in the body as energy reserves and that are important components of cell membranes.

Metabolism—The chemical processes within living organisms that are necessary to maintain life.

Mitochondria—The organelles in cells that produce energy through respiration.

Nucleic acids—Molecules such as DNA and RNA that are composed of chains of nucleotides.

Proteins—Chains of amino acids that form the structural components of cells, as well as enzymes, hormones, and antibodies, and which can serve as energy sources.

Stem cells—Unspecialized cells that give rise to differentiated cells and that have huge potential as treatments for diseases and disorders.

Urea—An end product of protein degradation that is excreted in the urine; the first biological molecule to be synthesized in the laboratory.

can also synthesize a multitude of new proteins with unique properties, merging biochemistry with biotechnology. Biochemists also study gene mutations that can cause cancer and other diseases and develop gene therapies for treating diseases and medical conditions.

At the cellular level, biochemists study the structures of cells and all of their components, including the nucleus that houses the DNA-containing chromosomes, the mitochondria that produce cellular energy, and chloroplasts in plant cells that convert sunlight into the energy that ultimately powers all of life. Lipids that form the membranes for enclosing cells and cell organelles and provide the frameworks for many of the metabolic activities of cells, as well as forming steroid hormones, are another important field of study. Biochemists research the channels, pumps, and specialized transporters that move molecules in and out of cells through membranes, as well as membrane receptors—proteins in membranes that receive molecular signals from other cells and other parts of the body. Finally, biochemistry includes the study of cell cycles, sensory systems, antibodies and the immune system, molecular motors, and signal transduction—the mechanisms by which cells communicate.

Purpose

Biochemistry underlies virtually all of the processes that take place in the human body. Thus, human health is essentially a question of biochemistry, and all human diseases have biochemical components. Clinical biochemistry is the branch of the science that develops and performs tests on various aspects of human biochemistry. Clinical biochemistry includes a wide range of laboratory tests and procedures, such as tests of liver function, measurements of the levels of enzymes and their activities, detection of specific proteins and other biomarkers that are indicative of various diseases, and the screening of newborns for common biochemical problems. Clinical biochemistry

WWW.BOOKBAZ.IR

involves identifying and quantifying chemicals and physiological processes in bodily fluids, such as blood, serum, plasma, and urine, as well as in tissues. Clinical biochemists research the effects of foods, drugs, hormones, and other substances on body tissues and biological processes. They also develop tests for detecting and monitoring diseases, genetic disorders, and other conditions, and analyzing the results of treatments. Clinical biochemists monitor the effects of therapeutic drugs, perform tests for the presence of illegal substances in the body, and develop new drugs

Chemical toxicology is a branch of biochemistry that measures the concentrations of various toxins in bodily fluids and tissues and identifies molecules in the environment that may be toxic to humans.

Virtually all human diseases and disorders have a biochemical component. Some diseases, such as diabetes and cardiovascular disease, are complex disorders of metabolism. There are many diseases that are inherited metabolic disorders, such as abnormalities in lipid metabolism. Examples of conditions with underlying biochemical causes include:

- diabetes mellitus and hypoglycemia
- gastrointestinal disorders and abnormalities in nutrient absorption
- kidney disease
- hyperuricemia and gout
- acid-base disorders
- disorders affecting the balance of electrolytes such as calcium, phosphate, and magnesium
- pituitary abnormalities and thyroid disease
- adrenal disease
- reproductive hormone disorders

The biochemistry of viruses, bacteria, and other pathogens and their effects on human health are important fields of research. The biochemistry underlying **aging**, stem cells, cancers, Alzheimer's disease, and **obesity**, and the effects of **exercise** on the biochemistry of the body are all very active areas of research.

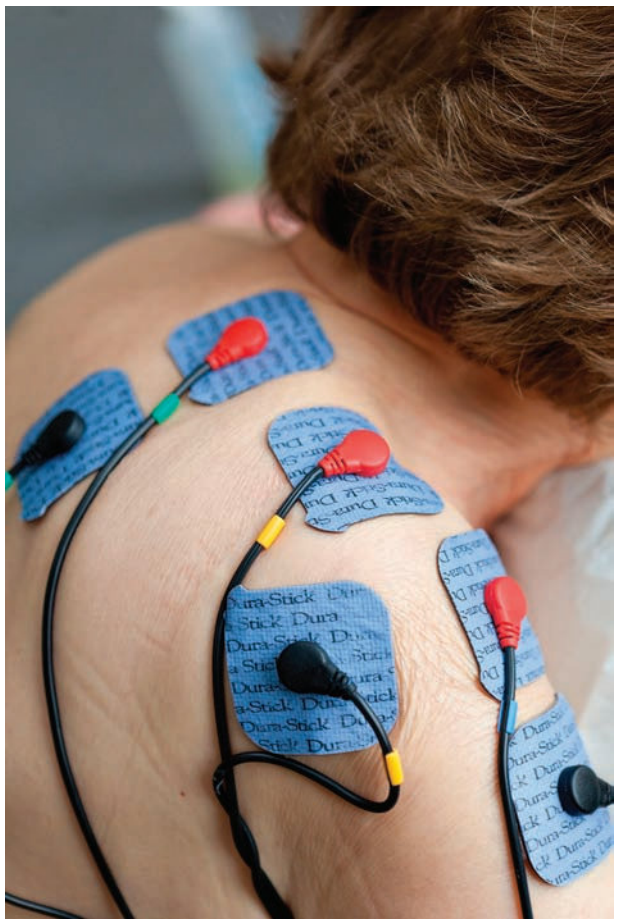
Bioelectric therapy

Definition

Bioelectric therapy is treatment that applies localized electrical stimulation to the body. It is a broad term used for a variety of different treatments, most often for **pain management** and wound healing.

Purpose

The most common use of bioelectric therapy is in the treatment of acute and chronic **pain** conditions. Bioelectric therapy may enable people to reduce or eliminate their pain medications and the accompanying side effects. It is sometimes applied in the treatment of the following:



Treatment of osteoarthritis using bioelectric therapy. *(Media for Medical/Getty Images)*

- back pain
- muscle pain
- headaches and migraines
- temporomandibular joint (TMJ) syndrome (jaw pain)
- blood flow disorders in the arms or legs
- arthritis
- nervous system disorders such as diabetic neuropathy
- painful skin ulcers caused by poor circulation or scleroderma (a chronic thickening or hardening of the skin)
- complex regional pain syndrome (CRPS), also called reflex sympathetic dystrophy (RSD)—a chronic condition in which large numbers of nerve impulses are sent to the affected site and which appears to have multiple causes and symptoms

Transcutaneous **electrical nerve stimulation** (TENS) is a type of bioelectric therapy used to prevent migraines and to treat various conditions including:

- muscular pain
- osteoarthritis
- rheumatoid arthritis
- sciatica
- post-surgical pain

Bioelectric treatments have been widely used in **physical therapy** and sports medicine. Bioelectric therapy is used in physical **rehabilitationexercise** to evaluate, re-educate, strengthen, and exercise muscles and to increase joint range of motion. Subtetanic low-intensity neuromuscular electrical stimulation is used by some athletes to enhance post-exercise recovery. Bioelectric therapy is also sometimes used to help heal chronic **wounds**. It has even been used to treat cancer.

Description

Electric current has been used since the nineteenth century to treat pain, wounds, and other conditions, with varying degrees of success. There are a wide variety bioelectric therapy techniques and devices, most of which involve the application of a mild electrical current to the skin. These techniques are used by some mainstream medical professionals and physical therapists, as well as by naturopaths, chiropractors, and other alternative medicine practitioners. Electroacupuncture is considered a form of bioelectric therapy. Even simple massage—the passage of electrical current from the masseuse's hands to the patient's body—is sometimes considered to be bioelectric therapy. Bioelectric therapy devices for home use are sometimes advertised as massagers.

Pain relief

Bioelectric therapy may relieve pain by stimulating nerves to block pain signals before they reach the brain. The therapy may also stimulate the release of endorphins, the body's natural painkillers. Alternatively, bioelectric therapy may simply distract the brain from the perception of pain by overloading it with nerve impulses.

In a typical bioelectric therapy procedure, several small, flat, rubber adhesive discs (electrodes) or rubber suction cups are applied to the skin at the areas to be treated. The electrodes or probes vary in size. They are connected to a computer that regulates the exact dosage of alternating current. Typical therapies use low-grade electrical stimuli or microcurrents of 200–600 microamperes (uA) with frequencies ranging from 0.3 to 80 hertz (Hz). This is similar to the electrical current in cells of the body. The current moves rapidly through the skin, and the body's response to the electrical stimulation is

WWW.BOOKBAZ.IR

measured. The electric current may feel like a mild, vibrating or tingling sensation that can be relaxing or soothing and provide pain relief. If the sensation is too strong, the current can be adjusted down. Treatments generally require multiple sessions of about 20 minutes each. A typical treatment course begins with five sessions the first week, followed by three sessions a week for a total of 16–20 sessions. Response varies with the individual patient and their condition.

Sympathetic therapy is a type of bioelectric therapy in which electrical current is administered through the peripheral nerves of the lower legs and feet and arms and hands to stimulate the sympathetic nervous system. This is believed to normalize the system to relieve chronic intractable pain. Sympathetic therapy generally uses eight electrodes placed at specific points on the feet, legs, arms, and hands to create four stimulation channels with frequencies varying from 0–1,000 Hz. There are hundreds of specific treatment protocols that can be adjusted during the treatment, which lasts about one hour. Following approximately ten professional treatments, a companion home device can be used. These devices have been approved by the U.S. Food and Drug Administration (FDA) for managing post-traumatic or post-surgical pain or relieving symptoms of chronic intractable pain.

A bioelectric nerve block or electroanalgesic nerve block stops nerve transmissions. It may be administered by a trained healthcare provider or by a device implanted in the body. It has been used for managing both acute and chronic cancer and non-cancer pain. It uses much higher frequencies than TENS and other bioelectric therapies.

TENS

TENS uses electrical impulses to stimulate nerve endings near or at the site of pain, replacing the pain with a tingling or massaging sensation. Although sometimes used in a healthcare setting, TENS is generally used in the home, enabling patients to control the length and intensity of the therapy. A TENS device consists of an adjustable power source about the size of a cell phone attached to electrodes via wires. The electrodes are made with adhesive cloth or foam and come in a variety of shapes. A gel applied to the skin under the electrode improves the current flow. The electrodes are placed on or adjacent to the painful area: the user experiments to find the sites that provide the most relief. Sometimes the electrodes are placed over a nerve related to the painful nerve or at a trigger point or **acupuncture** points. Conventional TENS devices generally have a frequency or pulse-per-second (pps) range of 2–150 Hz, an intensity range of 1–80 milliamps (mA), and a pulse duration of 50–250 microseconds. The electrodes are usually left in place for long periods of time, with the device turned on for about 30 minutes at a time.

Acupuncture-type TENS—also called percutaneous electrical nerve stimulation (PENS) or electroacupuncture—is a combination of electrical stimulation and acupuncture, in which the electrical current is passed through acupuncture needles inserted into the skin instead of electrodes attached to the skin. It uses low-frequency (2–5 Hz), high-intensity electrical pulses of longer duration, which some patients find more effective or longer lasting but others find uncomfortable.

In 2014, the FDA approved a TENS device for migraine prevention. It is used before the onset of pain and is the first medical device approved for preventing migraines. This battery-powered plastic headband is worn like a pair of glasses against the forehead and is available with a doctor's prescription. It works on the trigeminal nerve that transmits migraine pain. The device is used for about 20 minutes daily and creates a tingling or massage-like sensation.

Wound healing

The theory behind bioelectric therapy for wound healing is that inflammation in chronic wounds reduces the flow of physiologic current through the injured tissue and prevents the cells from removing toxins and taking in nutrients required for healing. Bioelectric therapy is believed to increase current flow, protein synthesis, and the production of energy (ATP) to stimulate the healing process. A similar theory applies to the use of bioelectric therapy for cancer treatment.

For treating pressure or leg **ulcers**, one electrode is usually in contact with the skin at the edge of the wound, and the other electrode is in contact with fluids in the wound bed. The electrodes are connected to a battery with control circuitry for applying the current. The current can be of high or low voltage and direct, alternating, or pulsed current. Direct current flows in one direction and is of a low intensity similar to that of the wound itself (1–10 uA). Alternating current reverses direction many times per second. Pulsed current may be direct or alternating and is delivered in microsecond or millisecond pulses. Bioelectric wound-care dressings are also available.

Transcranial direct current stimulation (tDCS)

Transcranial direct current stimulation (tDCS) is the passage of very low-level electrical current through specific areas of the brain. Still in the research stage,

tDCS studies suggest that it may improve cognitive and motor function and mood. The current is believed to be below the level at which neurons in the brain fire. As of 2014, about 30 clinics in the United States offered tDCS, generally in a research setting.

Precautions

Bioelectric therapy is generally regarded as safe, at least when used in healthcare settings. It appears to help relieve pain in some people but not in others. The pain relief is usually short term; for example, TENS often relieves pain for the duration of the treatment and possibly a while longer. Thus for most types of pain, bioelectric therapy must be part of a more comprehensive pain-management program.

Bioelectric therapy is not recommended during **pregnancy** or for people who have certain types of **pacemakers**, **blood clots** in the arms or legs (thrombosis), or bacterial infections. Bioelectric therapy can cause skin irritation and **itching** and redness under the electrodes, which may be relieved by changing the type of electrode or gel. Electrical stimulation should never be applied to the front of the neck, where it could stimulate nerves that affect the heart rhythm.

Preparation

Patients taking insulin or blood-thinning medications may be given specific instructions to follow before a bioelectric therapy session. Practitioners may also ask patients to fast before the procedure.

Aftercare

Following some types of bioelectric therapy sessions, patients may need someone to drive them home.

Risks

The only risks from professional bioelectric therapy are possible redness and skin irritation beneath the electrodes. Homemade bioelectric therapy devices—and possibly some devices available over the internet or from other sources—may not be safe, and users may be at risk for serious **burns** or other injury. The long-term effects of therapies such as tDCS are unknown.

Research and general acceptance

There have been very few controlled, randomized clinical trials of various types of bioelectric therapy. Although much of the medical establishment considers bioelectric treatments to be of questionable value, many people have found relief from pain with bioelectric therapy. Some authorities claim that it can reduce the required dosage of pain medications by as much as 50%. Others believe that it is of most benefit for mild muscle pain or arthritis and of less benefit for inflamed joints or rheumatoid arthritis.

- TENS results vary greatly, but enough patients get pain relief with TENS that many doctors recommend it as part of an overall pain management program.
- A clinical study of the TENS migraine-prevention device found that it reduced the average number of days with migraines from 6.94 to 4.88 per month.
- Some studies have indicated that bioelectric stimulation therapy can heal one-third of chronic, non-healing wounds of more than six months duration in elderly patients, within 16 weeks of beginning the therapy.

KEY TERMS

Complex regional pain syndrome (CRPS)—Severe, chronic, often burning pain in an extremity, typically occurring after an injury and accompanied by various other symptoms.

Electro-acupuncture—Percutaneous electrical nerve stimulation (PENS); acupuncture in which a weak electrical current is passed through acupuncture needles inserted in the skin.

Endorphins—A class of peptides in the brain that bind to opiate receptors, resulting in pleasant feelings and pain relief.

Hertz (Hz)—A unit of frequency; 1 Hz is equal to one cycle per second.

Microampere (uA)—A unit of current equal to one millionth of an ampere.

Neuropathy—A usually degenerative disorder of the nerves or nervous system.

Reflex sympathetic dystrophy (RSD)—A type of complex regional pain syndrome without identifiable peripheral nerve injury.

Sympathetic nervous system—The fight-or-flight division of the autonomic nervous system that increases heart rate, blood pressure, and respiratory rate, among other functions, in active or stressful situations.

Transcranial direct current stimulation (tDCS)—The passage of very low-level electrical current through specific areas of the brain to improve cognitive or motor function or treat mental disorders.

Transcutaneous electrical nerve stimulation (TENS)—A mild electric current passed through the skin to relieve pain.

WWW.BOOKBAZ.IR

- Studies have found tDCS to be useful for treating people with stroke, Parkinson disease, depression, and obsessive-compulsive disorder.

Margaret Alic, PhD

Biofeedback

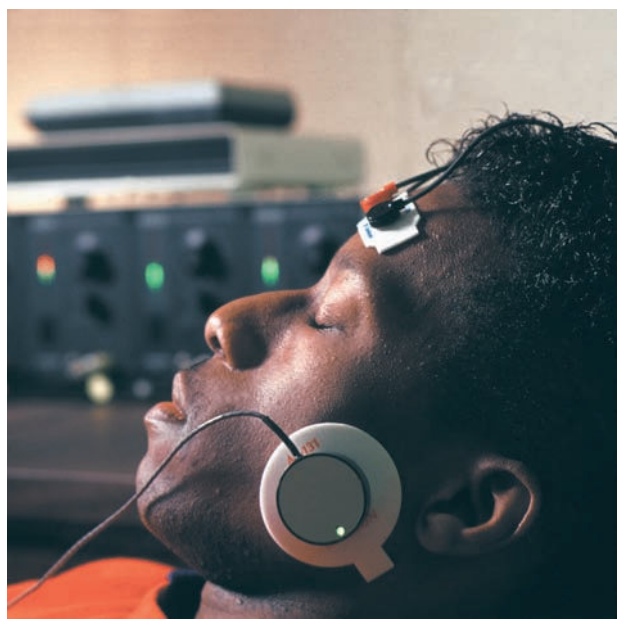
Definition

Biofeedback, or applied psychophysiological feedback, is a patient-guided treatment that teaches an individual to control muscle tension, **pain**, body temperature, brain waves, and other bodily functions and processes through relaxation, visualization, and other cognitive control techniques. The name biofeedback refers to the biological signals that are fed back, or returned, to the patient in order for the patient to develop techniques of manipulating them.

Purpose

Biofeedback has been used to successfully treat a number of disorders and their symptoms, including temporomandibular joint disorder (TMJ), chronic pain, **irritable bowel syndrome** (IBS), Raynaud's syndrome, **epilepsy**, attention-deficit hyperactivity disorder (**ADHD**), migraine headaches, **anxiety**, depression, **traumatic brain injury**, and **sleep disorders**.

Illnesses that may be triggered at least in part by **stress** are also targeted by biofeedback therapy. Certain types of headaches, high blood pressure, **bruxism** (teeth grinding), **post-traumatic stress disorder**, **eating disorders**, substance abuse, and some **anxiety disorders** may be treated successfully by teaching patients the ability to relax and release both muscle and mental tension.



A patient undergoing biofeedback therapy. *(Photo Researchers, Inc.)*

Biofeedback is often just one part of a comprehensive treatment program for some of these disorders.

NASA has used biofeedback techniques to treat astronauts who suffer from severe space sickness, during which the autonomic nervous system is disrupted. Scientists at the University of Tennessee have adapted these techniques to treat individuals suffering from severe **nausea and vomiting** that is also rooted in autonomic nervous system dysfunction.

Recent research also indicates that biofeedback may be a useful tool in helping patients with **urinary incontinence** regain bladder control. Individuals learning pelvic-floor muscle strengthening exercises can gain better control over these muscles by using biofeedback. Sensors are placed on the muscles to train the patient where they are and when proper contractions are taking place.

Description

Origins

In 1961, Neal Miller, an experimental psychologist, suggested that autonomic nervous system responses (for instance, heart rate, blood pressure, gastrointestinal activity, regional blood flow) could be under voluntary control. As a result of his experiments, he showed that such autonomic processes were controllable. This work led to the creation of biofeedback therapy. Willer's work was expanded by other researchers. Thereafter, research performed in the 1970s by UCLA researcher Dr. Barry Sterman established that both cats and monkeys could be trained to control their brain wave patterns. Sterman then used his research techniques on human patients with epilepsy, where he was able to reduce seizures by 60% with the use of biofeedback techniques. Throughout the 1970s, other researchers published reports of their use of biofeedback in the treatment of cardiac **arrhythmias**, headaches, Raynaud's syndrome, and excess stomach acid, and as a tool for teaching deep relaxation. Since the early work of Miller and Sterman, biofeedback has developed into a frontline behavioral treatment for an even wider range of disorders and symptoms.

During biofeedback, special sensors are placed on the body. These sensors measure the bodily function that is causing the patient problem symptoms, such as heart rate, blood pressure, muscle tension (EMG or electromyographic feedback), brain waves (EEC or electroencophalographic feedback), respiration, and body temperature (thermal feedback), and translates the information into a visual and/or audible readout, such as a paper tracing, a light display, or a series of beeps.

While the patient views the instantaneous feedback from the biofeedback monitors, he or she begins to recognize what thoughts, fears, and mental images influence his or her physical reactions. By monitoring this relationship between mind and body, the patient can then use these same thoughts and mental images as subtle cues, as these act as reminders to become deeply relaxed, instead of anxious. These reminders also work to manipulate heartbeat, brain wave patterns, body temperature, and other bodily functions. This is achieved through relaxation exercises, mental imagery, and other cognitive therapy techniques.

As the biofeedback response takes place, patients can actually see or hear the results of their efforts instantly through the sensor readout on the biofeedback equipment. Once these techniques are learned and the patient is able to recognize the state of relaxation or visualization necessary to alleviate symptoms, the biofeedback equipment itself is no longer needed. The patient then has a powerful, portable, and self-administered treatment tool to deal with problem symptoms.

Biofeedback that specializes in reading and altering brain waves is sometimes called *neurofeedback*. The brain produces four distinct types of brain waves—delta, theta, alpha, and beta—that all operate at a different frequency. Delta, the slowest frequency wave, is the brain wave pattern associated with sleep. Beta waves, which occur in a normal, waking state, can range from 12–35 Hz. Problems begin to develop when beta wave averages fall in the low end (underarousal) or the high end (overarousal) of that spectrum. Underarousal might be present in conditions such as depression or attention-deficit disorder, and overarousal may be indicative of an anxiety disorder, **obsessive-compulsive disorder**, or excessive stress. Beta wave neurofeedback focuses on normalizing that beta wave pattern to an optimum value of around 14 Hz. A second type of neurofeedback, alpha-theta, focuses on developing the more relaxing alpha (8-13 Hz) and theta waves (4-9 Hz) that are usually associated with deep, meditative states, and has been used with some success in substance abuse treatment.

Through brain wave manipulation, neurofeedback can be useful in treating a variety of disorders that are suspected or proven to impact brain wave patterns, such as epilepsy, attention-deficit disorder, migraine headaches, anxiety, depression, traumatic brain injury, and sleep disorders. The equipment used for neurofeedback usually uses a monitor as an output device. The monitor displays specific patterns that the patient attempts to change by producing the appropriate type of brain wave. Or, the monitor may reward the patient for producing the appropriate brain wave by producing a positive reinforcer, or reward. For example, children may be rewarded with a series of successful moves in a displayed video game.

WWW.BOOKBAZ.IR

Depending on the type of biofeedback, individuals may need up to 30 sessions with a trained professional to learn the techniques required to control their symptoms on a long-term basis. Therapists usually recommend that their patients practice both biofeedback and relaxation techniques on their own at home.

Preparations

Before initiating biofeedback treatment, the therapist and patient will have an initial consultation to record the patient's medical history and treatment background and discuss goals for therapy.

Before a neurofeedback session, an EEG is taken from the patient to determine his or her baseline brainwave pattern.

Biofeedback typically is performed in a quiet and relaxed atmosphere with comfortable seating for the patient. Depending on the type and goals of biofeedback being performed, one or more sensors will be attached to the patient's body with conductive gel and/or adhesives. These may include:

- Electromyographic (EMG) sensors. EMG sensors measure electrical activity in the muscles, specifically muscle tension. In treating TMJ or bruxism, these sensors would be placed along the muscles of the jaw. Chronic pain might be treated by monitoring electrical energy in other muscle groups.
- Galvanic skin response (GSR) sensors. These are electrodes placed on the fingers that monitor perspiration, or sweat gland, activity.
- Temperature sensors. Temperature, or thermal, sensors measure body temperature and changes in blood flow.
- Electroencephalography (EEG) sensors. These electrodes are applied to the scalp to measure the electrical activity of the brain, or brain waves.
- Heart rate sensors. A pulse monitor placed on the finger tip can monitor pulse rate.
- Respiratory sensors. Respiratory sensors monitor oxygen intake and carbon dioxide output.

Precautions

Individuals who use a pacemaker or other implantable electrical devices should inform their biofeedback therapist before starting treatments, as certain types of biofeedback sensors have the potential to interfere with these devices.

Biofeedback may not be suitable for some patients. Patients must be willing to take a very active role in the treatment process. And because biofeedback focuses strictly on behavioral change, those patients who wish to gain insight into their symptoms by examining their past might be better served by psychodynamic therapy.

Biofeedback may also be inappropriate for cognitively impaired individuals, such as those patients with organic brain disease or a traumatic brain injury, depending on their levels of functioning.

Patients with specific pain symptoms of unknown origin should undergo a thorough medical examination before starting biofeedback treatments to rule out any serious underlying disease. Once a diagnosis has been made, biofeedback can be used concurrently with conventional treatment.

Biofeedback may only be one component of a comprehensive treatment plan. For illnesses and symptoms that are manifested from an organic disease process, such as cancer or diabetes, biofeedback should be an adjunct to (complementary to), and not a replacement for, conventional medical treatment.

Side effects

There are no known side effects to properly administered biofeedback or neurofeedback sessions.

Research and general acceptance

Preliminary research indicates that neurofeedback may be a promising new tool in the treatment of **schizophrenia**. Researchers reported that schizophrenic patients had used neurofeedback to simulate brain wave patterns that antipsychotic medications produce in the brain. Further research is needed to determine what impact this may have on treatment for schizophrenia.

The use of biofeedback techniques to treat an array of disorders has been extensively described in the medical literature. Controlled studies for some applications are limited, such as for the treatment of menopausal symptoms and premenstrual disorder (PMS). There is also some debate over the effectiveness of biofeedback in ADHD treatment, and the lack of controlled studies on that application. While many therapists, counselors, and mental health professionals have reported great success with treating their ADHD patients with neurofeedback techniques, some critics attribute this positive therapeutic impact to a placebo effect.

There may also be some debate among mental health professionals as to whether biofeedback should be considered a first line treatment for some mental illnesses, and to what degree other treatments, such as medication, should be employed as an adjunct therapy.

Biomedical engineering

Definition

Biomedical engineering, also known as bioengineering, is the application of engineering principles to the study of medical and biological problems. The goal of biomedical engineering is to use electrical, chemical, and mechanical engineering principles to conduct studies and develop tools that can aid in the biomedical care of patients.

Description

Biomedical engineering can trace its history back far as a hundred years ago, when the first x-ray machines and electrocardiographs dramatically illustrated how technology could be applied toward the diagnosis of disease. Today, the field of biomedical engineering is in full flower, propelled by the momentum of the post-World War II technology boom and the latest molecular, genetic, and computational developments. Having gone beyond its roots in imaging and instrumentation, biomedical engineering now encompasses many specialties, including

- biomechanics, which is the application of classical mechanics (the study of how objects move in response to forces placed on them) to biomedical problems. Biomechanics uses the principles of mechanics to blood movement throughout the body, the effect of injuries on the shape and mechanics of body parts, and the mechanics of body movement (e.g. how an arm is lifted, or how a person walks). Biomechanics has contributed to an understanding of the mechanical function of the bones, cartilage, and soft tissue in the musculoskeletal system, as well as an understanding of other major organ systems, such as the heart, lungs, and blood vessels.
- prosthetic devices and artificial organs. These may include prosthetics ranging from replacements for missing fingers to an exoskeleton that can help paraplegic persons walk; and artificial organs, such as hearts and lungs.
- biomaterials, which are living and artificial materials that can be used in implantation. Biomaterials science focuses on the body's biochemical interactions with the implant materials. Implant material are typically chemically inert, non-toxic, non-carcinogenic, and resilient enough to endure a lifetime of chemical and mechanical forces; and may include such materials as ceramics, polymers, metal alloys, and composite materials. Research into nanomaterials (materials with at least one dimension fewer than about 100 nm) is an increasingly important area of research, because nanomaterials have a high ratio of surface area to volume, and because of that, have unusual chemical and physical properties that engineers can tap for various applications, including tissue regeneration.
- biomedical instrumentation, or bioinstrumentation, which uses mechanical, electrical, and optical principles and systems to monitor the body's physiologic status. Many of the physiologic changes that occur in the body are mediated by electrical signals: Different ions (charged elements or molecules) are allowed to flow into and out of cells at different times, depending on cellular and systemic demands. Biomedical instrumentation attempts to infer aspects of the body's physiologic state by measuring and interpreting these electrical signals. It includes biomedical measurement, as well as the development of devices to control and guide biomedical processes through mechanical or electrical means (e.g., cardiac pacemakers and respirators).
- biosensors, which focus on the development and instrumentation of measurement systems. Some new biosensors, for instance, look like temporary tattoos. These biosensors stick to the skin and take physiologic measurements, such as heart rate. Other new sensors are designed to measure drugs and biomolecules in patients' blood to diagnose diseases early in their progress when they are easier to treat and to help physicians customize pharmacological regimes to the patient. Additional sensors are also becoming available for connection to and use with smart phones.
- biorobotics, which are biologically-inspired robots that have mobility and flexibility, as well as the potential for sensory capabilities. This area has

WWW.BOOKBAZ.IR

Campbell Aird demonstrates the use of his robot arm after cancer required amputation. *(Tom Kidd / Alamy)*

many applications, including tools that help a patient perform tasks that they otherwise cannot perform; the development of advanced prosthetics that the patient can control and move; devices to measure the state and/or progress of a disease in a patient; or interactive training or education for patients (and family members) or clinicians.

- medical imaging, which uses energy phenomena, physics principles, and high-speed data processing to reveal the anatomic structure and physiologic function of the body. Medical imaging includes x-ray applications (mammography, angiography), ultrasound, computer tomography (CT), magnetic resonance imaging (MRI), single-photon emission computed tomography (SPECT), and positron emission tomography (PET). Each of these technologies is based on exploiting an understanding of electromagnetic or sound energy patterns to provide images of not readily observable aspects of body structure and function.
- physiologic modeling, simulation, and control, also known as systems physiology, which attempts to provide formal quantitative models of the various systems of the body, whether they be at the cellular level, the organ level, or the full-body level. Using experimental data and mathematical models, system physiology relies on computer simulation to describe and understand human physiology. These models provide a basis for thinking about how the body functions in an integrated way. Systems physiology is the source of such models as cardiovascular models, respiratory models, neural network models, and biochemical metabolic models.
- biotechnology, also known as cellular, tissue, and genetic engineering, is the study of how biological materials can be modified at a cellular level for useful ends. It studies the biochemistry and physics of cells to develop beneficial interventions and biomedical research and diagnostic tools. A sprawling specialty, this includes such developments as new diagnostic tests for diseases, miniature devices that can deliver therapeutic drugs to specific sites, and synthetic vaccines and therapeutic proteins.

- rehabilitation engineering, which focuses on developing tools for cognitive and physical rehabilitation, particularly those technologies that assist mobility and communication. These include the development of rehabilitation prosthetics, the design of living space modifications, the development of transportation alternatives, and the design of hardware and software to aid in communication and cognitive rehabilitation.
- clinical engineering, which focuses on how the latest biomedical technologies are used in a clinical setting. This may include the adaptation of biomedical technologies to the needs of the hospital and clinicians, the management of medical instrumentation and equipment, and the interface between the medical instrumentation and the clinical software that records data of interest to the hospital. Patient safety and progress are also important aspects of clinical engineering.
- medical informatics, which is the study of how information is used and disseminated in healthcare settings. Medical informatics includes the study of health information systems, computer networks in clinical settings, and clinical decision systems. As of 2014, a growing number of hospitals and medical offices are utilizing electronic health records (EHRs) in lieu of the traditional paper patient records. EHRs may allow clinicians to retrieve additional healthcare data about a patient (such as information from a second healthcare provider, or results of a lab test) to aid in the patient's overall care. Telemedicine is a growing field. This encompasses the use of communications systems to permit remote consultations and access to expertise, which is especially important to health care in rural or economically disadvantaged areas where access to doctors is lacking.

Purpose

The Engineering in Medicine and Biology Society, part of the Institute of Electrical and Electronic Engineers (IEEE), describes biomedical engineering as working: "at the intersection of engineering, the life sciences, and healthcare. These engineers take principles from applied science (including mechanical, electrical, chemical and computer engineering) and physical sciences (including physics, chemistry and mathematics) and apply them to biology and medicine.."

Because of the multidisciplinary nature of biomedical engineering, individuals in this profession typically have training that combines engineering and medical aspects. Many universities now offer biomedical or bioengineering degrees. Upon graduation, students may find work in a variety of private and public sector settings. These include laboratory, clinical, software-development, or a managerial/administrative settings in biomedical device firms, pharmaceutical companies, hospitals, research facilities, universities, and government agencies.

The demand for biomedical engineers is expected to grow, according to the U.S. Bureau of Labor Statistics. The bureau projects that employment of biomedical engineers will grow 27 % from 2012 to 2022, which is described as "much faster than the average for all occupations.". It attributes this increase to the aging population and its assumed need more medical care, and to the "increased public awareness of biomedical engineering advances and their benefits."

As scientific and technological advances in molecular and cell biology, materials science, computer science, and other disciplines continue, the field of biomedical engineering will likewise expand, providing new healthcare tools and treatment options for patients throughout the world.

Bipolar disorder

Definition

Bipolar disorder, formerly known as manic depression, is a psychiatric disorder characterized by severe and unusual changes in energy level, mood, and interactions with others. The mood swings associated with bipolar disorder are unpredictable and range from **mania** (elevated or irritable mood) to depression (a mood characterized by loss of interest and sadness). Bipolar disorder causes significant impairment in social, occupational, and general functioning.

Demographics

According to the National Institutes of Mental Health (NIMH), bipolar disorder affected about 5.7 million Americans, 2.6% of the U.S. population age 18 and older in 2013. Other statistics suggest that 1.0% of the population has bipolar disorder type I, and 1.1% of the population has bipolar disorder type II. About another 2.4–4.7% of the population has subthreshold bipolar disorder, meaning that they show characteristics of the disorder that do not rise to the level of formal diagnosis. Internationally the lifetime prevalence of reported bipolar disorder ranges from 0.3–1.5%.

No racial differences in distribution exist. While bipolar type I occurs equally in both sexes, bipolar II and rapid-cycling bipolar disorder are more common in females than in males. The average age of onset of bipolar disorder is 25; however, about 1% of adolescents and between 0.2% and 0.4% of children have been diagnosed with the bipolar disorder. Controversy exists about diagnosing the disorder in these groups. Because of the complexity of the disorder, a correct diagnosis can be delayed, and between 20% and 30% of adults with bipolar disorder report having undiagnosed symptoms in childhood or adolescence.

Description

Bipolar disorder is characterized by alternating manic episodes in which the individual feels abnormally euphoric, optimistic, and energetic, and depressive periods in which the individual feels sad, hopeless, guilty, and sometimes suicidal. Manic or depressive periods may last for days, weeks, or months and run the spectrum from mild to severe. These episodes may be separated by periods of emotional stability in which the individual functions normally.

Bipolar I disorder is characterized by at least one manic episode without a major depressive episode. Manic episodes are the "high" of the manic-depressive cycle. A person experiencing a manic episode often has feelings of self-importance, elation, talkativeness, increased sociability, and a desire to embark on goal-oriented activities, coupled with the characteristics of irritability, impatience, impulsiveness, hyperactivity, and a decreased need for sleep. Usually this manic period is followed by a period of severe depression, although a few individuals may not experience a major depressive episode. Mixed states, where both manic or hypomanic symptoms and depressive symptoms occur at the same time, also may occur (e.g., racing thoughts of mania with the listlessness of depression). Also, dysphoric mania is common particularly in adolescents. This is mania characterized by anger and irritability.

Bipolar II disorder is characterized by major depressive episodes alternating with episodes of hypomania, a milder form of mania. A bipolar depressive episode may be difficult to distinguish from a unipolar major depressive episode. Patients with bipolar

depression tend to have extremely low energy, slowed mental and physical processes, and more profound **fatigue** (for example, hypersomnia, a sleep disorder marked by a need for excessive sleep or sleepiness when awake) than people with unipolar depression.

Cyclothymia refers to the cycling of hypomanic episodes with less severe depression that does not reach major depressive proportions. Some people with cyclothymia develop bipolar I or II disorder later in life.

A phenomenon known as rapid cycling occurs in up to 20% of bipolar individuals. In rapid cycling, at least four manic and depressive mood swings must occur within 12 months. In some cases of ultra-rapid cycling, the individual may bounce between manic and depressive states several times within a 24-hour period. This condition is very hard to distinguish from mixed states.

Risk factors

According to the Mayo Clinic, 60% of bipolar cases have a family history of the disease. The Child and Adolescent Bipolar Foundation (CABF) reports that the risk for a child of one bipolar parent to develop the disorder is 15%–30%. If both parents have bipolar disorder, the risk for each child increases to 50%–75%. The risk in siblings and fraternal twins is 15%–25%. The risk in identical twins, who share the same genes, is approximately 70%. Research in identical twins indicates that both genes and other factors play a role in developing bipolar disorder.

Women who have given birth may also be at increased risk of developing subsequent episodes in the immediate period after giving birth.

Causes and symptoms

Possible causes

Although the source of bipolar disorder has not been clearly identified, a number of genetic and environmental factors appear to be involved in triggering episodes. Bipolar disorder has an inherited component. As noted above, children who have at least one parent with bipolar disorder are more likely to develop the disorder. They are also more likely to be diagnosed with other psychiatric disorders such as attention deficit/hyperactivity disorder (**ADHD**). Several studies have uncovered possible genetic connections to the predisposition for bipolar disorder. A large study done in Sweden reported in 2009 that **schizophrenia** and bipolar disorder appeared to share similar genetic causes.

No specific gene mutations have been identified that consistently show up in bipolar patients. However, there appears to be a potential genetic correlation between bipolar disorder and mutations in specific regions of chromosomes 13, 18, and 21. The building blocks of genes, called nucleotides, are normally arranged in a specific order and quantity. If these nucleotides are repeated in a redundant fashion, a genetic abnormality often results. Some evidence exists for an abnormal type of nucleotide sequence (CAG/CTG repeats) on chromosome 18 in patients with bipolar II disorder. However, not all bipolar patients have this mutation, and the presence of this sequence does not worsen the disorder or change the age of onset.

People with bipolar disorder tend to have other psychiatric disorders. **Oppositional defiant disorder** (ODD) and ADHD are among the most common. Over half of patients diagnosed with bipolar disorder have a history of substance abuse. A high rate of association exists between cocaine abuse and bipolar disorder. The emotional and physical highs and lows of cocaine use correspond to the manic depression cycle of the bipolar patient, making the disorder difficult to diagnoses.

For some bipolar patients, manic and depressive episodes coincide with seasonal changes. Depressive episodes are typical during winter and fall, and manic episodes are more probable in the spring and summer months.

Brain imaging studies suggest that there are physical changes in the brains of people with bipolar disorder. It is hypothesized that dopamine and other neurotransmitters involved in mood may be involved. The possible role of hormonal imbalances in bipolar disorder is another area of investigation. Further research is needed to determine which genes are involved in bipolar disorder. It is likely that both genetic and environmental factors contribute to the disease.

Symptoms

Bipolar disorder causes recurrent dramatic mood swings that range from a manic high to a depressive low. There are often periods of normal mood in between episodes of mania and depression. Severe changes in energy and behavior accompany the swings in mood.

Manic episode symptoms include:

- increased energy, activity, and restlessness
- excessively high, euphoric mood
- extreme irritability and reactivity
- racing thoughts and fast speech that jump from one topic to another, known as flight of ideas
- distractibility due to unimportant events and the inability to concentrate

WWW.BOOKBAZ.IR

- reduced perceived need for sleep
- unrealistic beliefs in one's abilities, powers, or importance
- poor judgment and impulsive behaviors
- increased sexual drive
- provocative, intrusive, or aggressive behavior
- denial that anything is wrong

Depressive episode symptoms include:

- persistent sad, anxious, or empty mood
- feelings of irritability, hopelessness, or negative mood
- feelings of guilt, worthlessness, or helplessness
- inability to take pleasure in activities
- fatigue
- inability to concentrate
- extreme sleep patterns
- extreme appetite changes that result in weight change
- chronic pain or physical discomfort in the absence of physical illness or injury
- thoughts of or attempts at suicide

Some people with bipolar II disorder have depressive episodes concurrent with mood reactivity (mood improves with positive event), and can switch from depression to hypomania. Hypomania is characterized by a mild or moderate level of mania. Because hypomania is less severe, it may be associated with increased functioning and enhanced productivity. However, hypomania is not a normal state of mind. Without proper treatment, hypomania may eventually progress into severe mania or switch into depression. Severe episodes of mania or depression may also include symptoms of **psychosis**. Psychotic symptoms include visual or auditory **hallucinations** and **delusions** (illogical, false, but strongly held beliefs). Psychotic symptoms in bipolar disorder tend to reflect the current extreme mood episode. During mania, psychotic delusions may include grandiosity, such as believing one has special powers of flight or extreme financial wealth or power. During depressive episodes, delusions may include paranoid fears of being poisoned or the belief that one has committed a terrible crime. Because of these psychotic symptoms, bipolar disorder is sometimes mistaken for schizophrenia.

Some people with bipolar disorder present with a mixed state of symptoms. A mixed bipolar state is characterized by symptoms of agitation, sleeplessness, appetite changes, psychosis, and suicidal tendencies. A depressed and hopeless mood may occur in conjunction with extreme energy. Signs of bipolar disorder may also be demonstrated outside of mental illness symptoms in behaviors such as alcohol or drug abuse, poor work performance, strained interpersonal relationships, or excessive promiscuity. Symptoms of bipolar disorder with postpartum onset usually occur within four weeks after **childbirth**. Bipolar disorder with a seasonal pattern displays symptoms related to seasonal change and latitude. The prevalence of the season-specific bipolar symptoms increases with higher latitudes and winter months.

Bipolar symptoms often present differently in children and adolescents. Manic episodes in these age groups are typically characterized by more psychotic features than in adults, which may lead to a misdiagnosis of schizophrenia. Children and adolescents also tend toward irritability and aggressiveness instead of elation. Further, symptoms tend to be chronic (ongoing), rather than acute (episodic). Bipolar children are easily distracted, impulsive, and hyperactive, which can lead to a misdiagnosis of ADHD. Furthermore, their aggression often leads to violence, which may be misdiagnosed as a **conduct disorder**. Complicating the picture is that ADHD and conduct disorders are often present concurrently in children with bipolar disorder.

Diagnosis

Bipolar disorder usually is diagnosed and treated by a psychiatrist and/or a psychologist with medical assistance. In addition to an interview, several clinical inventories or scales may be used to assess the patient's mental status and determine the presence of bipolar symptoms. These include the Millon Clinical Multiaxial Inventory III (MCMI-III), **Minnesota Multiphasic Personality Inventory** II (MMPI-2), the Internal State Scale (ISS), the Self-Report Manic Inventory (SRMI), and the Young Mania Rating Scale (YMRS). The tests are verbal and/or written and are administered in both hospital and outpatient settings. Laboratory tests for drug and alcohol may be done to rule out other causes of the behavior.

Psychologists and psychiatrists typically use the criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) published by the American Psychiatric Association to definitively diagnose bipolar disorder. The *DSM-5* describes a manic episode as an abnormally elevated or irritable mood lasting a period of at least one week that is distinguished by at least three of the mania symptoms: inflated self-esteem, decreased need for sleep, talkativeness, racing thoughts, distractibility, increase in goal-directed activity, or excessive involvement in pleasurable activities that have a high potential for painful consequences. If the mood of the patient is irritable and not elevated, four of the symptoms are required. *DSM-5* differs from its predecessor, *DSM-IV*, in requiring also

KEY TERMS

Cyclothymia—A milder form of bipolar disorder characterized by alternating hypomania and less severe depressive episodes.

Dopamine—A neurotransmitter and the precursor of norepinephrine.

Neuroprotective—Conveying some form of protection to the nervous system from injury.

Neurotransmitter—One of a group of chemicals secreted by a nerve cell (neuron) to carry a chemical message to another nerve cell, often as a way of transmitting a nerve impulse. Examples of neurotransmitters include acetylcholine, dopamine, serotonin, and norepinephrine.

Nucleotides—Building blocks of genes, which are arranged in specific order and quantity.

Off-label use—Drugs legally prescribed by physicians for non-FDA approved uses. It is not legal for pharmaceutical companies to advertise drugs for uses not approved by the FDA. Companies to advertise drugs for off-label uses.

Rapid cycling—Four or more manic, hypomanic, mixed, or depressive episodes within a 12-month period.

Schizophrenia—A severe mental disorder in which a person loses touch with reality and may have illogical thoughts, delusions, hallucinations, behavioral problems, and other disturbances.

Selective serotonin reuptake inhibitors (SSRIs)—A class of antidepressants that work by blocking the reabsorption of serotonin in brain cells, raising the level of the chemical in the brain. SSRIs comprise such drugs as Prozac, Zoloft, Luvox, and Paxil.

that a patient demonstrate actual physical behaviors corresponding to these moods, rather than simply the moods themselves.

Although some clinicians find the criteria too rigid, a hypomanic diagnosis requires a duration of at least four days with at least three of the symptoms indicated for manic episodes (four if mood is irritable and not elevated). The *DSM-5* notes that unlike manic episodes, hypomanic episodes do not cause a marked impairment in social or occupational functioning, do not require hospitalization, and do not have psychotic features. In addition, because hypomanic episodes are characterized by high energy and goal-directed activities, often result in a positive outcome, and are perceived in a positive manner by the patient (e.g., as a time of heightened creativity or work output), bipolar II disorder can go undiagnosed.

Substance abuse, thyroid disease, and use of prescription or over-the-counter medication can mask or mimic the presence of bipolar disorder. In cases of substance abuse, the patient must undergo a period of **detoxification** and abstinence before a mood disorder is diagnosed and treatment begins.

Treatment

Drugs

Medication is the most effective treatment for bipolar disorder. A combination of mood stabilizing agents with antidepressants, antipsychotics, and anticonvulsants may be used for long-term regulation of manic and depressive episodes. In the acute phase, the choice of medication for bipolar disorder is dependent on the stage or type of current episode. Many drugs are used to treat an acute manic episode, primarily the antipsychotics and **benzodiazepines** (e.g., lorazepam, clonazepam). In the presence of psychotic symptoms, atypical antipsychotics may be used to treat psychotic symptoms and acute mania, and may contribute to mood stabilization. For depressive episodes, antidepressants may be used. Medications may be added temporarily, to treat episodes of mania or depression that break through despite mood-stabilizer treatment.

Mood stabilizing drugs dampen the extremes of manic and depressive episodes. Lithium (Cibalith-S, Eskalith, Lithane, Lithobid, Lithonate, Lithotabs) was the first mood stabilizer approved by the United States Food and Drug Administration (FDA) for the treatment of mania and the prevention of both manic and depressive episodes. Lithium is a first-line medication used in the long-term preventative treatment of extreme mood episodes in bipolar disorder. It has been demonstrated to play a neuroprotective role in brain function. Because lithium takes up to ten days to reach a therapeutic level in the bloodstream, it sometimes is prescribed in conjunction with neuroleptics and/or benzodiazepines to provide more immediate relief of a manic episode. Lithium also has been shown to be effective in regulating bipolar depression, but it is not

WWW.BOOKBAZ.IR

recommended for mixed mania. Lithium may not be an effective long-term treatment option for rapid cyclers, who typically develop a tolerance for it or may not respond to it. Possible side effects of the drug include weight gain, thirst, nausea, and hand **tremors**. Prolonged lithium use also may cause **hyperthyroidism** (a disorder in which the thyroid is overactive, which may cause heart **palpitations**, nervousness, the presence of **goiter**, sweating, and a wide array of other symptoms) and abnormalities in liver function.

In addition to lithium, the following drugs are commonly used to treat bipolar disorders:

- Carbamazepine (Tegretol, Atretol) is an anticonvulsant drug often prescribed in conjunction with other mood stabilizing agents. The drug may be used to treat bipolar patients who have not responded well to lithium therapy. Blurred vision and abnormal eye movement are two possible side effects of carbamazepine therapy.
- Valproate (divalproex sodium, or Depakote; valproic acid, or Depakene) is one of the few drugs available that has been proven effective in treating rapid cycling bipolar and mixed states patients. Valproate is prescribed alone or in combination with carbamazepine and/or lithium. Stomach cramps, indigestion, diarrhea, hair loss, appetite loss, nausea, and unusual weight loss or gain are some of the common side effects of valproate.
- Risperidone (Risperdal) may be used for short-term (usually no more than 3 weeks) treatment of acute mania associated with bipolar disorder. It may be given in conjunction with lithium or valproate. Side effects include weight gain, sedation, and abnormally low blood pressure upon rising from lying down (orthostatic hypotension).
- Quetiapine (Seroquel) is a newer antipsychotic that acts on neurotransmitters in the brain. It appears to have fewer side effects than some of the older antipsychotics.
- Olanzapine (Zyprexa, Zydis) may be used to treat acute manic episodes in individuals with bipolar I. Its mechanism of action is not clear. Side effects include orthostatic hypotension (low blood pressure when rising to a standing position).
- Symbyax, a combination of olanzipine and fluoxetine, was approved by the FDA in 2004 as the first drug to specifically treat bipolar disorder.

Because antidepressants may stimulate manic episodes in some bipolar patients, their use in bipolar disorder, once common, is now controversial. They are typically used as short-term treatment. Antidepressants are not specifically approved for treating depression associated with bipolar disorder but may be prescribed off-label. **Selective serotonin reuptake inhibitors** (SSRIs) or, less often, **monoamine oxidase inhibitors** (MAO inhibitors) may be prescribed for episodes of bipolar depression. Tricyclic antidepressants used to treat unipolar depression may trigger rapid cycling in bipolar patients and are, therefore, not a preferred treatment option for bipolar depression. Antidepressants commonly prescribed for bipolar disorder include:

- SSRIs such as fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil) regulate depression by regulating levels of serotonin, a neurotransmitter. Anxiety, diarrhea, drowsiness, headache, sweating, nausea, sexual problems, and insomnia are all possible side effects of SSRIs.
- MAOIs such as tranylcypromine (Parnate) and phenelzine (Nardil) block the action of monoamine oxidase (MAO), an enzyme in the central nervous system. Patients taking MAOIs must cut foods high in tyramine (found in aged cheeses and meats) out of their diet to avoid hypotensive side effects.
- Bupropion (Wellbutrin) is a heterocyclic antidepressant. The exact neurochemical mechanism of the drug is not known, but it has been effective in regulating bipolar depression in some patients. Side effects of bupropion include agitation, anxiety, confusion, tremor, dry mouth, fast or irregular heartbeat, headache, and insomnia.

Other drugs may be used in conjunction with a long-term pharmaceutical treatment plan.

- Long-acting benzodiazepines such as clonazepam (Klonapin) and alprazolam (Xanax) may be used for rapid treatment of manic symptoms to calm and sedate patients until mania or hypomania have waned and mood-stabilizing agents can take effect. Sedation is a common effect, and clumsiness, lightheadedness, and slurred speech are other possible side effects of benzodiazepines.
- Neuroleptics such as chlorpromazine (Thorazine) and haloperidol (Haldol) also may be used to control mania while a mood stabilizer such as lithium or valproate takes effect. Because neuroleptic side effects can be severe (difficulty in speaking or swallowing, paralysis of the eyes, loss of balance control, muscle spasms, severe restlessness, stiffness of arms and legs, tremors in fingers and hands, twisting movements of body, and weakness of arms and legs), benzodiazepines are generally preferred over neuroleptics.
- Clozapine (Clozaril) is an atypical antipsychotic medication used to control manic episodes in patients who have not responded to typical mood stabilizing

agents. The drug has also been a useful prophylactic, or preventative treatment, in some bipolar patients. Common side effects of clozapine include tachycardia (rapid heart rate), hypotension, constipation, and weight gain. Agranulocytosis, a potentially serious but reversible condition in which the white blood cells that typically fight infection in the body are destroyed, is a possible side effect of clozapine. Patients treated with the drug should undergo weekly blood tests to monitor white blood cell counts.

Electroconvulsive therapy

Electroconvulsive therapy (ECT) has been successful in treating both unipolar and bipolar depression and mania. However, ECT usually is employed after all pharmaceutical treatment options have been explored in patients with severe depression and suicidal thoughts. ECT is given under **anesthesia** and patients are given a muscle relaxant medication to prevent convulsions. The treatment consists of a series of electrical pulses that move into the brain through electrodes on the patient's head. Although the exact mechanisms behind the success of ECT therapy are not known, it is believed that this electrical current alters the electrochemical processes of the brain, consequently relieving depression. Headaches, muscle soreness, nausea, and confusion are possible side effects immediately following an ECT procedure. Temporary **memory loss** has also been reported in ECT patients. In bipolar patients, ECT is often used in conjunction with drug therapy.

Psychosocial interventions

Psychosocial interventions include both patient education and **psychotherapy**. It is important for patients to receive social support and illness management skills. Family and friends must be aware of the high rates of social dysfunction and marital discord. Involvement in national support groups is advisable (i.e., National Depressive and Manic-Depressive Association).

Psychoeducation usually focuses on all of the following:

- assessment of what parameters will have an impact on the outcome of patient's disease
- implementing the boundaries and requirements of treatment
- implementation of a personal cost-benefit analysis concerning specific treatment directions
- implementing a follow-up program
- implementing future directions, which may include adjustment or change interventions

Genetic counseling should be included in family education programs since the predisposition for this disorder has been genetically proven to increase among first-degree relatives.

Alternatives

Alternative treatments for bipolar disorder generally are complementary treatments to conventional therapies. General recommendations for controlling bipolar symptoms include maintaining a calm environment, avoiding overstimulation, getting plenty of rest, regular **exercise**, and eating a healthy diet.

Chinese herbs may help to soften mood swings. **Traditional Chinese medicine** (TCM) remedies are prescribed based on the patient's overall constitution and the presentation of symptoms. These remedies can help to stabilize moods, not just treat swings in mood. A TCM practitioner might recommend a mixture called the Iron Filings Combination, which includes the Chinese herbs asparagus, ophiopogon, fritillaria, arisaema, orange peel, polygala, acorus, forsythia, hoelen, fu-shen, scrophularia, uncaria stem, salvia, and iron filings, to treat certain types of mania in the bipolar patient. There are other formulas for depression. A trained practitioner should guide all of these remedies.

Acupuncture can be used for treatment to help maintain a more even temperament.

Biofeedback is effective in helping some patients control symptoms such as irritability, poor self-control, racing thoughts, and sleep problems.

A diet low in vanadium, a mineral found in meats and other foods, and high in vitamin C may be helpful in reducing depression.

Individuals using herbal remedies in addition to traditional pharmaceuticals should tell their physician, as some herbal remedies interact with conventional drugs, either heightening or depressing their effect. Recommended herbal remedies to ease depressive episodes may include damania (*Turnera diffusa*), **ginseng** (*Panax ginseng*), kola (*Cola nitida*), lady's slipper (*Cypripedium calceolus*), lavender (*Lavandula angustifolia*), lime blossom (*Tilia x vulgaris*), oats (*Avena sativa*), rosemary (*Rosmarinus officinalis*), skullcap (*Scutellaria laterifolia*), St. John's wort (*Hypericum perforatum*), valerian (*Valeriana officinalis*), and vervain (*Verbena officinalis*).

Prognosis

While most patients will show some positive response to treatment, response varies widely, from full recovery to a complete lack of response to all

WWW.BOOKBAZ.IR

drug and/or ECT therapy. Drug therapies frequently need adjustment to achieve the maximum benefit for the patient. Bipolar disorder is a chronic, recurrent illness in over 90% of people with the disorder. The disorder requires lifelong observation and treatment after diagnosis. According to the World Health Organization, bipolar disorder is the sixth leading cause of disability worldwide

Suicide is the major complication of bipolar disorder, and is related to the duration of the depressive episode. Between 25% and 50% of individuals with bipolar disorder attempt suicide, and 11% complete the suicide attempt. The longer the depressive episode lasts, the higher the risk of suicidal tendencies. Alcoholics and patients with other chronic medical diseases are particularly prone to planning and implementing a suicide attempt.

The four main groups that are likely to carry out a suicide attempt include the following:

- Individuals who are overwhelmed by life problems. Suicide attempts in this group tend to be related to aggression and impulsive behaviors, not significant depressive episodes
- Individuals who are attempting to control others
- Individuals who are chronically ill with another medical disease
- Individuals with other severe types of psychotic illness, delusions, and paranoia

Prevention

The ongoing medical management of bipolar disorder is critical to preventing relapse, or recurrence, of manic episodes. Even in carefully controlled treatment programs, bipolar patients may experience recurring episodes of the disorder. Patient education in the form of psychotherapy or self-help groups is crucial for training bipolar patients to recognize signs of mania and depression and to take an active part in their treatment program.

Birth defects

Definition

Birth defects are physical abnormalities that are present at birth; they also are called congenital abnormalities. More than 3,000 have been identified.

Description

Birth defects are found in 2–3% of all newborn infants. This rate doubles in the first year, and reaches 10% by age five, as more defects become evident and can be diagnosed. Almost 20% of deaths in newborns are caused by birth defects.

Abnormalities can occur in any major organ or part of the body. Major defects are structural abnormalities that affect the way a person looks and require medical and/or surgical treatment. Minor defects are abnormalities that do not cause serious health or social problems. When multiple birth defects occur together and have a similar cause, they are called syndromes. If two or more defects tend to appear

Congenital absence of three fingers. Deformities such as this are usually caused by damage to the developing fetus *in utero*. *(Dr. P. Marazzi/Photo Researchers, Inc.)*

Prevalence of common birth defects in the United States

Approximately 120,000 babies are born with a birth defect in the United States each year.

Type of defect	Number of infants affected each year
Congenital heart defects	40,000
Down syndrome	6,000
Spinda bifida	1,500–2,000
Orofacial clefts (e.g., cleft lip, cleft palate)	6,800

SOURCE: March of Dimes. "Birth defects." Available online at: http://marchofdimes.org/baby/birth-defects.aspx (accessed September 5, 2014).

(Table by PreMediaGlobal. © Cengage Learning®)

together but do not share the same cause, they are called associations.

Causes and symptoms

The specific cause of many congenital abnormalities is unknown, but several factors associated with **pregnancy** and delivery can increase the risk of birth defects.

Teratogens

Any substance that can cause abnormal development of the egg in the mother's womb is called a teratogen. In the first two months after conception, the developing organism is called an embryo; developmental stages from two months to birth are called fetal. Growth is rapid, and each body organ has a critical period in which it is especially sensitive to outside influences. About 7% of all congenital defects are caused by exposure to teratogens.

DRUGS. Only a few drugs are known to cause birth defects, but all have the potential to cause harm. For example, in 2003, a study found that use of topical (local) **corticosteroids** in the first trimester of pregnancy may be associated with **cleft lip**. Thalidomide is known to cause defects of the arms and legs; several other types also cause problems, such as:

- Alcohol. Drinking large amounts of alcohol while pregnant causes a cluster of defects called fetal alcohol syndrome, which includes intellectual disabilities (ID), heart problems, and growth deficiency. Binge drinking early in pregnancy is dangerous even if the woman quits drinking later.
- Antibiotics. Certain antibiotics are known tetratogens. Tetracycline affects bone growth and discolors the teeth. Drugs used to treat tuberculosis can lead to hearing problems and damage to a nerve in the head (cranial damage).
- Anticonvulsants. Drugs given to prevent seizures can cause serious problems in the developing fetus, including ID and slow growth. Studies in the United Kingdom and Australia have tracked the percentage of birth defects caused by certain antiepileptic drugs.
- Antipsychotic and antianxiety agents. Several drugs given for anxiety and mental illness are known to cause specific defects.
- Antineoplastic agents. Drugs given to treat cancer can cause major congenital malformations, especially central nervous system defects. They also may be harmful to the healthcare worker who is giving them while pregnant.
- Hormones. Male hormones may cause masculinization of a female fetus. A synthetic estrogen (DES) given in the 1940s and 1950s caused an increased risk of cancer in the adult female children of the mothers who received the drug.
- Recreational drugs. Drugs such as LSD have been associated with arm and leg abnormalities and central nervous system problems in infants. Crack cocaine also has been associated with birth defects. Since drug abusers tend to use many drugs and have

WWW.BOOKBAZ.IR

poor nutrition and prenatal care, it is hard to determine the effects of individual drugs.

CHEMICALS. Environmental chemicals such as fungicides, food additives, and pollutants are suspected of causing birth defects, though this is difficult to prove.

RADIATION. Exposure of the mother to high levels of radiation can cause small skull size (microcephaly), blindness, **spina bifida**, and **cleft palate**. How severe the defect is depends on the duration and timing of the exposure.

INFECTIONS. Three viruses are known to harm a developing baby: **rubella**, cytomegalovirus (CMV), and herpes simplex. *Toxoplasma gondii,* a parasite that can be contracted from undercooked meat, from dirt, or from handling the feces of infected cats, causes serious problems. Untreated **syphilis** in the mother also is harmful.

Genetic factors

A gene is a tiny, invisible unit containing information (DNA) that guides how the body forms and functions. Each individual inherits tens of thousands of genes from each parent, arranged on 46 chromosomes. Genes control all aspects of the body, how it works, and all its unique characteristics, including eye color and body size. Genes are influenced by chemicals and radiation, but sometimes changes in the genes are unexplained accidents. Each child gets half of its genes from each parent. In each pair of genes one will take precedence (dominant) over the other (recessive) in determining each trait, or characteristic. Birth defects caused by dominant inheritance include a form of dwarfism called **achondroplasia**; high **cholesterol**; Huntington's disease, a progressive nervous system disorder; **Marfan syndrome**, which affects connective tissue; some forms of **glaucoma**, and **polydactyly** (extra fingers or toes).

If both parents carry the same recessive gene, they have a one-in-four chance that the child will inherit the disease. Recessive diseases are severe and may lead to an early death. They include sickle cell anemia, a blood disorder that commonly affects persons of African descent, and **Tay-Sachs disease**, which causes ID in people of eastern European Jewish heritage. Two recessive disorders more common in Caucasians are **cystic fibrosis**, a lung and digestive disorder, and **phenylketonuria** (PKU), a metabolic disorder. If only one parent passes along the genes for the disorder, the normal gene received from the other parent will prevent the disease, but the child will be a carrier. Having the gene is not harmful to the carrier, but there is the 25% chance of the genetic disease showing up in the child of two carriers.

Some disorders are linked to the sex-determining chromosomes passed along by parents. **Hemophilia**, a condition that prevents blood from clotting, and Duchenne **muscular dystrophy**, which causes muscle weakness, are carried on the X chromosome. Genetic defects also can take place when the egg or sperm are forming if the mother or father passes along some faulty gene material. This is more common in older mothers. The most common defect of this kind is **Down syndrome**, a pattern of intellectual disabilities and physical abnormalities, often including heart defects, caused by inheriting three copies of a chromosome rather than the normal pair.

A less understood cause of birth defects results from the interaction of genes from one or both parents plus environmental influences. These defects are thought to include:

- Cleft lip and palate, which are malformations of the mouth.
- Clubfoot, ankle or foot deformities.
- Spina bifida, an open spine caused when the tube that forms the brain and spinal chord does not close properly.
- Water on the brain (hydrocephalus), which causes brain damage.
- Diabetes mellitus, an abnormality in sugar metabolism that appears later in life.
- Heart defects.
- Some forms of cancer.

A serious illness in the mother, such as an underactive thyroid, or **diabetes mellitus**, in which her body cannot process sugar, also can cause birth defects in the child. In fact, in 2003, it was shown that babies of diabetic mothers are five times as likely to have structural heart defects as other babies. An abnormal amount of amniotic fluid may indicate or cause birth defects. Amniotic fluid is the liquid that surrounds and protects the unborn child in the uterus. Too little of this fluid can interfere with lung or limb development. Too much amniotic fluid can accumulate if the fetus has a disorder that interferes with swallowing. In 2003, a study linked the mother's weight to risk of birth defects. Obese women were about three times more likely to have an infant with spina bifida or omphalocele (protrusion of part of the intestine through the abdominal wall) than women of average weight. Women who were overweight or classified as obese also were twice as likely to have an infant with a heart defect or multiple birth defects than women classified as average weight.

Diagnosis

If there is a family history of birth defects or if the mother is over 35 years old, then screening tests can be done during pregnancy to gain information about the health of the baby.

- Alpha-fetoprotein test. This is a simple blood test that measures the level of a substance called alpha-fetoprotein that is associated with some major birth defects. An abnormally high or low level may indicate the need for further testing.
- Ultrasound. The use of sound waves to examine the shape, function, and age of the fetus is a common procedure. It also can detect many malformations, such as spina bifida, limb defects, and heart and kidney problems. In 2003, researchers in England announced a new combination of blood tests and ultrasound to detect Down syndrome sooner and more accurately than with the usual blood screenings done at 20 weeks of pregnancy.
- Amniocentesis. This test usually is done between the 13th and 15th weeks of pregnancy. A small sample of amniotic fluid is withdrawn through a thin needle inserted into the mother's abdomen. Chromosomal analysis can rule out Down syndrome and other genetic conditions.
- Chorionic villus sampling (CVS). This test can be done as early as the ninth week of pregnancy to identify chromosome disorders and some genetic conditions. A thin needle is inserted through the abdomen or a slim tube is inserted through the vagina that takes a tiny tissue sample for testing.

If a birth defect is suspected after a baby is born, then confirmation of the diagnosis is very important. The patient's medical records and medical history may hold essential information. A careful **physical examination** and laboratory tests should be done. Special diagnostic tests also can provide genetic information in some cases. The March of Dimes, a nonprofit organization, recommends that every baby born in the United States receives, at minimum, screening for the same core group of birth defects including phenylketonuria, **congenital adrenal hyperplasia**, congenital hypothryroidism, biotinidase deficiency, and others. The goal of the recommendations is to unify screening procedures across the United States.

Treatment

Treatment depends on the type of birth defect and how serious it is. When an abnormality has been identified before birth, delivery can be planned at a healthcare facility that is prepared to offer any special care needed. Some abnormalities can be corrected with surgery. Experimental procedures have been used successfully in correcting some defects, like excessive fluid in the brain (**hydrocephalus**), even before the baby is born. Early reports have shown success with **fetal surgery** on spina bifida patients. By operating on these fetuses while still in the womb, surgeons have prevented the need for shunts and improved outcomes at birth for many newborns. However, long-term studies still are needed. Patients with complicated conditions usually need the help of experienced medical and educational specialists with an understanding of the disorder.

Prognosis

The prognosis for a disorder varies with the specific condition.

Prevention

Pregnant women should eat a nutritious diet. Taking **folic acid** supplements before and during pregnancy reduces the risk of having a baby with serious problems of the brain or spinal chord (neural tube defects). It is important to avoid any teratogen that can harm the developing baby, including alcohol and drugs. When there is a family history of congenital defects in either parent, **genetic counseling** and testing can help parents plan for future children. Often, counselors can determine the risk of a genetic condition occurring and the availability of tests for it. Talking to a genetic counselor after a child is born with a defect can provide parents with information about medical management and available community resources.

Birthmarks

Definition

Birthmarks, including angiomas and vascular malformations, are benign (noncancerous) skin growths composed of rapidly growing or poorly formed blood vessels or lymph vessels. Found at birth (congenital) or developing later in life (acquired) anywhere on the body, they range from faint spots to dark swellings covering wide areas.

Description

Skin angiomas, also called vascular (pertaining to vessel) nevi (marks), are composed of blood vessels (hemangiomas) or lymph vessels (lymphangiomas), that lie beneath the skin's surface. Hemangiomas, composed of clusters of cells that line the capillaries, the body's smallest blood vessels, are found on the face and neck (60%), trunk (25%), or the arms and legs (15%). Congenital hemangiomas, 90% of which appear at birth or within the first month of life, grow quickly, and disappear over time. They are found in 1–10% of full-term infants, and 25% of premature infants. About 65% are capillary hemangiomas (strawberry marks), 15% are cavernous (deep) hemangiomas, and the rest are mixtures. Hemangiomas are three times more common in girls. Usually, only one hemangioma is found; in 20% two are found, while fewer than 5% of affected infants have three or more. Lymphangiomas are skin bumps caused by enlarged lymph vessels anywhere on the body.

A fading capillary hemangioma on the nose of a child. *(Custom Medical Stock Photo, Inc.)*

Vascular malformations are poorly formed blood or lymph vessels that appear at birth or later in life. One type, the salmon patch (nevus simplex), a pink mark composed of dilated capillaries, is found on the back of the neck (also called a stork bite) in 40% of newborns, and on the forehead and eyelids (also called an angel's kiss) in 20%. Stork bites are found in 70% of white and 60% of black newborns.

Found in fewer than 1% of newborns, port-wine stains (nevus flammeus), are vascular malformations composed of dilated capillaries in the upper and lower layers of the skin of the face, neck, arms, and legs. Often permanent, these flat pink-to-red marks develop into dark purple bumpy areas in later life; 85% appear on only one side of the body.

Acquired hemangiomas include spider angiomas (nevus araneus), commonly known as spider veins, and cherry angiomas (senile angiomas or Campbell de Morgan spots). Found around the eyes, cheekbones, arms, and legs, spider angiomas are red marks formed from dilated blood vessels. They occur during **pregnancy** in 70% of white women and 10% of black women, in alcoholics and **liver disease** patients, and in 50% of children. Cherry angiomas, dilated capillaries found mainly on the trunk, appear in the 30s, and multiply with **aging**.

Causes and symptoms

There are no known causes for congenital skin angiomas; they may be related to an inherited weakness of vessel walls. Exposure to estrogen causes spider angiomas in pregnant women or those taking **oral contraceptives**. Spider angiomas tend to run in families, and may be associated with liver disease, sun exposure, and **trauma**.

Hemangiomas

Hemangiomas first appear as single or multiple, white or pale pink marks, ranging from 2–20 cm (average 2–5 cm) in size. Some are symptomless while others cause **pain** or bleeding, or interfere with normal

functioning when they are numerous, enlarged, infected, or ulcerated. Vision is affected by large marks on the eyelids. Spider and cherry angiomas are unsightly but symptomless.

Each type of hemangioma has a characteristic appearance:

- Capillary hemangiomas (strawberry marks). These round, raised marks are bright red and bumpy like a strawberry, and become white or gray when fading.
- Cavernous hemangiomas. These slightly raised, dome-shaped, blue or purple swellings are sometimes associated with lymphangiomas or involve the soft tissues, bone, or digestive tract.
- Spider angiomas. These are symptomless, reddish blue marks formed from blood-filled capillaries radiating around a central arteriole (small artery) in the shape of a spider web.
- Cherry angiomas. These harmless, dilated capillaries appear as tiny, bright red-to-violet colored bumps.
- Lymphangiomas. These dilated lymph vessels form light pink or yellow cysts (fluid-filled sacs) or swellings.

Vascular malformations

These are faint, flat, pink stains that grow as the child grows into larger dark red or purple marks. Some are symptomless but others bleed if enlarged or injured. Disfiguring port-wine stains can cause emotional and social problems. About 5% of port-wine stains on the forehead and eyelids increase eye pressure due to involvement of the eye and surrounding nerves. Abnormalities of the spinal cord, soft tissues, or bone may be associated with severe port-wine stains.

Each type has a characteristic appearance:

- Salmon patches. These symptomless, light red-to-pink marks usually fade with time.
- Port-wine stains. These flat, pink marks progress to raised, dark red-to-purple grape-like lumps distorting the facial features, arms, or legs.

Diagnosis

Patients are treated by pediatricians (doctors who specialize in the care of children), dermatologists (skin disease specialists), plastic surgeons (doctors who specialize in correcting abnormalities of the appearance), and ophthalmologists (eye disease specialists).

Angiomas and vascular malformations are not difficult to diagnose. The doctor takes a complete medical history and performs a **physical examination** including inspection and palpation of the marks. The skin is examined for discoloration, scarring, bleeding, infection, or ulceration. The type, location, size, number, and severity of the marks are recorded. The doctor may empty the mark of blood by gentle pressure. Biopsies or specialized x rays or scans of the abnormal vessels and their surrounding areas may be performed. Patients with port-wine stains near the eye may require **skull x rays**, **computed tomography scans**, and vision and central nervous system tests. Most insurance plans pay for diagnosis and treatment of these conditions.

Treatment

Treatment choices for skin angiomas and vascular malformations depend on their type, location, and severity, and whether they cause symptoms, pain, or disfigurement.

Watchful waiting

No treatment is given, but the mark is regularly examined. This continues until the mark disappears, or requires treatment. This approach is particularly appropriate for the treatment of hemangiomas, which often do not require treatment, since they eventually shrink by themselves.

Drugs

CORTICOSTEROIDS. Daily doses of the anti-inflammatory drugs prednisone or prednisolone are given for up to 2 months with gradual reduction of the dose. The marks begin to subside within 7–10 days, but may take up to 2 months to fully disappear. If no response is seen in 2 weeks, the drug is discontinued. Treatment may be repeated. Side effects include growth retardation, increased blood pressure and blood sugar, **cataracts**, glandular disorders, and infection. The **corticosteroids** triamcinolone acetate and betamethasone **sodium** phosphate or acetate are injected directly into the marks with a response usually achieved within a week; additional injections are given in 4–6 weeks. Side effects include tissue damage at the injection site.

INTERFERON ALPHA-2A. This drug reduces cell growth, and is used for vascular marks that affect vision and that are unresponsive to corticosteroids. Given in daily injections under the skin, a response rate of 50% is achieved after about 7 months. Side effects include **fever**, chills, muscle and joint pain, vision disorders, low white and red blood cell counts, **fatigue**, elevated liver enzymes, nausea, blood clotting problems, and nerve damage.

ANTIBIOTICS. Oral or topical (applied to the skin) **antibiotics** are prescribed for infected marks.

WWW.BOOKBAZ.IR

Surgery

LASER SURGERY. Lasers create intense heat that destroys abnormal blood vessels beneath the skin, without damaging normal skin. Two types of lasers are used: the flashlamp-pulsed dye laser (FPDL) and the neodymium:YAG (Nd:YAG) laser. The FPDL, used mainly for strawberry marks and port-wine stains, penetrates to a depth of 1.8 mm and causes little scarring, while the Nd:YAG laser penetrates to a depth of 6 mm, and is used to treat deep hemangiomas. **Laser surgery** is not usually painful, but can be uncomfortable. Anesthetic cream is used for FPDL treatment. Treatment with the Nd:YAG laser requires local or general **anesthesia**. Children are usually sedated or anesthetized. Healing occurs within 2 weeks. Side effects include bruising, skin discoloration, swelling, crusting, and minor bleeding.

SURGICAL EXCISION. Under local or general anesthesia, the skin is cut with a surgical instrument, and vascular marks or their **scars** are removed. The cut is repaired with stitches or skin clips.

CRYOSURGERY. Vascular marks are frozen with an extremely cold substance sprayed onto the skin. **Wounds** heal with minimal scarring.

ELECTRODESICCATION. Affected vessels are destroyed with the current from an electric needle.

Other treatments

These include:

- Sclerotherapy. Injection of a special solution causes blood clotting and shrinkage with little scarring. Side effects include stinging, swelling, bruising, scarring, muscle cramping, and allergic reactions. This treatment is used most commonly for spider angiomas.
- Embolization. Material injected into the vessel blocks blood flow, which helps control blood loss during surgery or reduces the size of inoperable growths. A serious side effect, stroke, can occur if a major blood vessel becomes blocked.
- Make-up. Special brands are designed to cover birthmarks (Covermark or Dermablend).
- Cleaning and compression. Bleeding marks are cleaned with soap and water or hydrogen peroxide, and compressed with a sterile bandage for 5-10 minutes.

Alternatives

Alternative treatments for strengthening weak blood vessels include eating high-fiber foods and foods containing bioflavonoids, including citrus fruit, blueberries, and cherries; supplementing the diet with vitamin C; and taking the herbs ginkgo (*Ginkgo biloba*) and bilberry (*Vaccinium myrtillus*.)

Prognosis

The various types of birthmarks have different prognoses:

- Capillary hemangiomas. Fewer than 10% require treatment. Without treatment, 50% disappear by age 5, 70% by age 7, and 90% by age 9. No skin changes are found in half while others have some discoloration, scarring, or wrinkling. Thirty percent to 90% respond to oral corticosteroids, and 45% respond to injected corticosteroids; 50% respond to interferon Alpha-2a. About 60% improve after laser surgery.
- Cavernous hemangiomas. Some do not disappear and some are complicated by ulceration or infection. About 75% respond to Nd:YAG laser surgery but have scarring. Severe marks respond to oral corticosteroids, but some require excision.
- Spider angiomas. These fade following childbirth and in children, but may recur. About 90% respond to sclerotherapy, electrodesiccation, or laser therapy.
- Cherry angiomas. These are easily removed by electrodesiccation.
- Lymphangiomas. These require surgery.
- Salmon patches. Eyelid marks disappear by 6–12 months of age, and forehead marks fade by age 6; however, 50% of stork bites on the neck persist into adulthood.
- Port-wine stains. Some flat birthmarks are easily covered with make-up. Treatment during infancy or childhood improves results. About 95% of the stains respond to FPDL surgery with minimal scarring; 25% will completely and 70% will partially disappear. For unknown reasons, 5% show no improvement.

Prevention

Congenital hemangiomas or vascular malformations cannot be prevented, but spider angiomas may be prevented by **exercise**, weight control, and a high-fiber diet, as well as avoidance of sun exposure, alcohol drinking, or wearing tight hosiery.

Bites and stings

Definition

Bites and stings are puncture injuries inflicted by an animal that penetrate the skin.

Demographics

The majority of animal bites in the United States come from dogs and cats. Many animal bites are never reported and never become infected. The Centers for Disease Control and Prevention (CDC) estimates that between three and six million animal bites occur annually in the United States. Dog bites account for 80%–90% of animal bites. In 2008 in the United States, about 885,000 dog bites required medical attention and 31,000 required **reconstructive surgery**. Cats account for only 5%–15% of animal bites, but 6% of cat bites require hospitalization compared to 1% of dog bites. The remainder of bites in the United States are caused mainly by small rodents (e.g., rabbits, rats and mice, ferrets).

Women are bitten by cats three times more often than men, while men are bitten by dogs three times more often than women. Children ages 5–9 have the highest incidence of animal bites. Animal bites account for about 1% of all emergency room visits. Dog bites kill between 10 and 20 people (most often children) annually in the United States.

An insect bite caused this person's lower lip to swell. *(Custom Medical Stock Photo, Inc.)*

Description

Humans can be injured by the bites or stings of many kinds of animals, including mammals such as dogs, cats, and fellow humans; arthropods such as spiders, bees, and wasps; snakes; and marine animals such as jellyfish and stingrays.

Mammals

DOGS. In the United States, where the dog population exceeds 75 million, dogs surpass all other mammals in the number of bites inflicted on humans; however, most dog-bite injuries are minor. Studies show that most dog bites are from pets or other dogs known to the bitten person. Nearly all of the injuries had by people seeking treatment in emergency rooms are of low severity, and most people are treated and released without being admitted to the hospital or sent to another facility. Many of the bites resulted from people attempting to break up fights between animals.

CATS. Although cats are found in nearly one-third of U.S. households, cat bites are far less common than dog bites. The tissue damage caused by cat bites is usually limited, but cat bites carry a high risk of infection. Whereas the infection rate for dog bite injuries is 15–20%, the infection rate for cat bites is 30–40%.

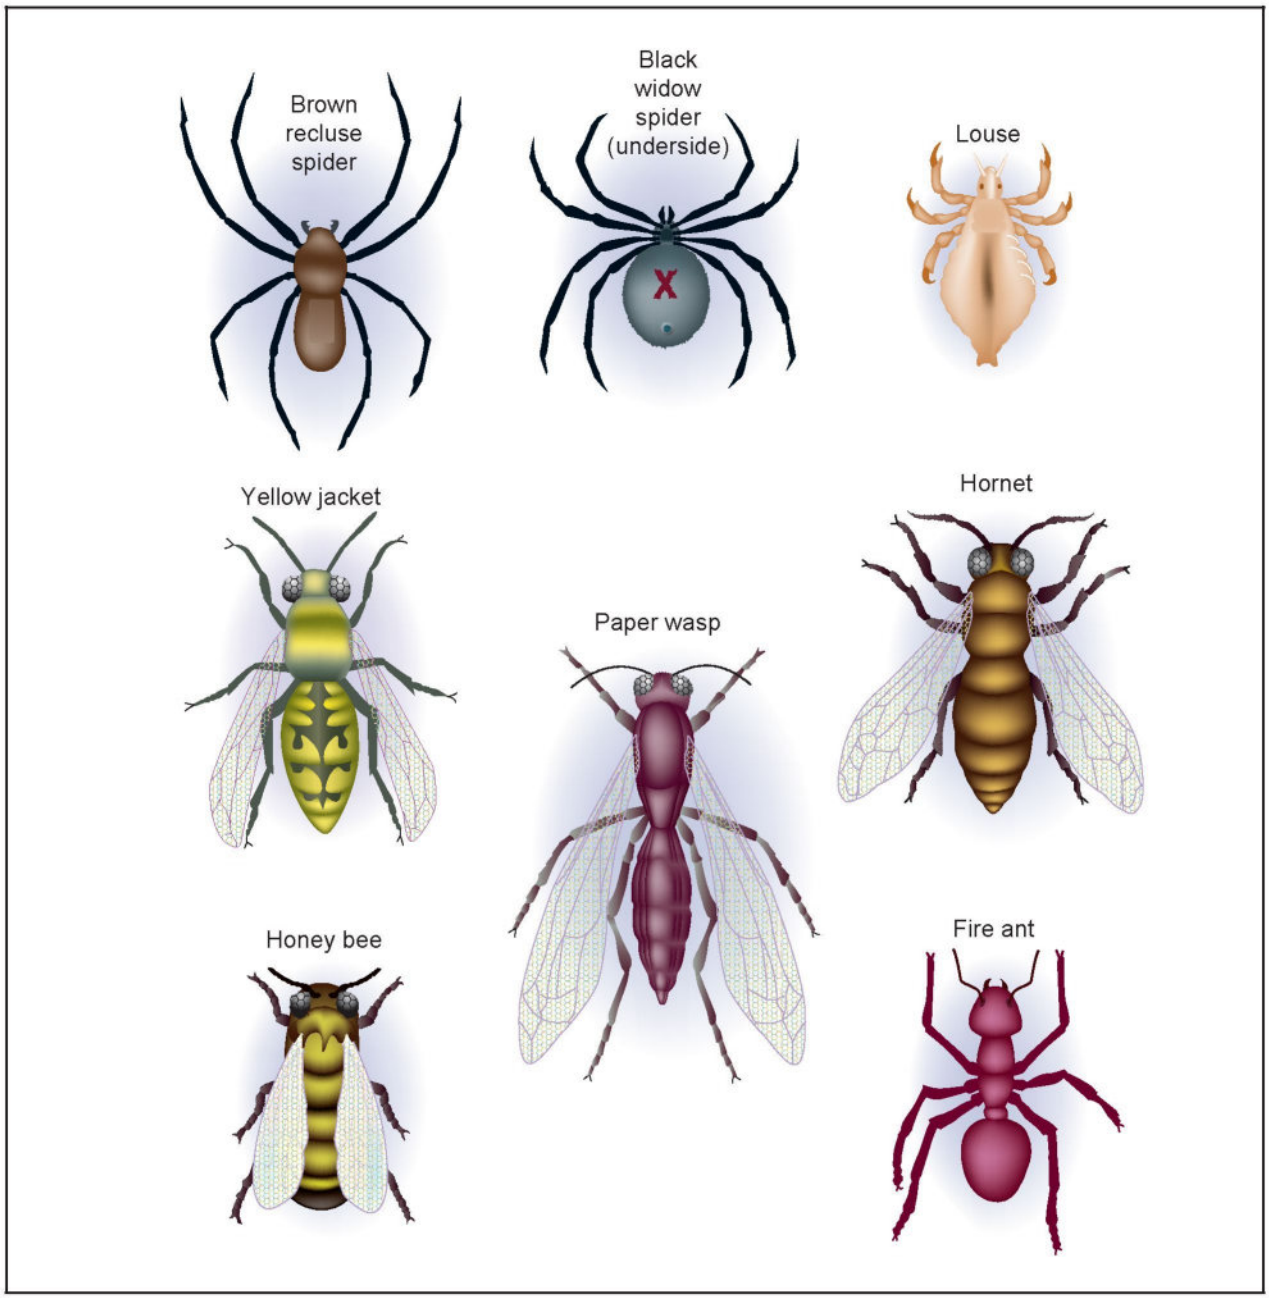
HUMANS. Bites from mammals other than dogs and cats are uncommon, with one exception—human bites. There are at least 70,000 human bites each year in the United States. Because the human mouth contains a multitude of potentially harmful microorganisms, human bites are more infectious than those of most other animals.

Arthropods

Arthropods are invertebrates belonging to the phylum Arthropoda, which includes insects, arachnids, crustaceans, and other subgroups. There are more than 700,000 species in all. The list of arthropods that bite or sting humans is extensive and includes lice, bedbugs, fleas, mosquitoes, black flies, ants, chiggers, ticks, centipedes, scorpions, and other species. Spiders, bees, and wasps are the three kinds of arthropod that most often bite people.

SPIDERS. In the United States, only two kinds of venomous spider are truly dangerous: widow spiders and brown (violin or fiddle) spiders. The black widow, which is found in every state except Alaska, is probably the most notorious widow spider. It prefers dark, dry places such as barns, garages, and outhouses, and also lives under rocks and logs. Disturbing a female

WWW.BOOKBAZ.IR



Types of spiders and insects that bite and sting. *(Illustration by Argosy, Inc. © Cengage Learning®)*

black widow or its web may provoke a bite. Brown spiders also prefer sheltered places, including clothing, and may bite if disturbed.

BEES AND WASPS. Bees and wasps will sting to defend their nests or if they are disturbed. Species common to the United States include honeybees, bumblebees, yellow jackets, bald-faced hornets, brown hornets, and paper wasps. Of note are also Africanized bee species, also called "killer bees," that have been found in the United States since 1990. More than 50 Americans die each year after being stung by a bee, wasp, or ant. Almost all of those deaths are the result of allergic reactions, and not of exposure to the venom itself.

Snakes

There are 20 species of venomous snakes in the United States. These snakes are found in every state except Maine, Alaska, and Hawaii. Each year about

8,000 Americans receive a snakebite; only four or five die, mostly from rattlesnake bites.

The venomous snakes of the United States are divided into two families, the Crotalidae (pit vipers) and the Elapidae. Pit vipers, named after the small heat-sensing pit that lies between each eye and nostril, are responsible for about 99% of the venomous snakebites experienced by Americans. Rattlesnakes, copperheads, and cottonmouths (also called water moccasins) are pit vipers. This family of snakes delivers its venom through two long, hinged fangs in the upper jaw. Some pit vipers carry potent venom that can threaten the brain and spinal cord. The venom of others, such as the copperheads, is less harmful.

The Elapidae family includes two kinds of venomous coral snakes indigenous to the southern and western states. Because coral snakes are bashful creatures that come out only at night, they almost never bite humans, and are responsible for approximately 25 bites a year in the United States. Coral snakes have short fangs and a small mouth, which lowers the risk of a bite actually forcing venom into a person's body. However, their venom is quite poisonous.

Marine animals

Several varieties of marine animal may bite or sting. Jellyfish and stingrays are two kinds that pose a threat to people who live or vacation in coastal communities.

Causes and symptoms

Dogs

A typical dog bite results in a laceration, tear, puncture, or crush injury. Bites from large, powerful dogs may cause **fractures** and dangerous internal injuries. Dogs trained to attack may bite repeatedly during a single episode. Infected bites usually cause **pain**, **cellulitis** (inflammation of the connective tissues), and a pus-filled discharge at the wound site within 8–24 hours. Many infections are confined to the wound site, but some of the microorganisms in the mouths of dogs can cause systemic and possibly life-threatening infections. Examples are **bacteremia** and meningitis—especially severe in people diagnosed with acquired **immunodeficiency** syndrome (**AIDS**) or other health conditions that increase their susceptibility to infection. **Rabies** is rare among pet dogs in the United States, most of which have been vaccinated against the disease. **Tetanus** is also rare but can be transmitted by a dog bite if the victim is not immunized.

Cats

The mouths of cats and dogs contain many of the same microorganisms. Cat scratches and bites are also capable of transmitting the *Bartonella henselae* bacterium, which can lead to **cat-scratch disease**, an unpleasant but usually not life-threatening illness.

A close-up view of lacerations on the shin of an adult woman inflicted by a Rottweiler dog. *(Custom Medical Stock Photo, Inc.)*

Cat bites are mostly found on the arms and hands. Sharp cat teeth typically leave behind a deep puncture wound that can reach muscles, tendons, and bones, which are vulnerable to infection because of their comparatively poor blood supply. This is why cat bites are much more likely to become infected than dog bites. Also, people are less inclined to view cat bites as dangerous and requiring immediate attention; the risk that infection has set in by the time a medical professional is consulted is thus greater.

Humans

Humans bites result from fights, sexual activity, medical and dental treatment, and seizures. Bites raise the possibility of spousal or **child abuse**. Children often bite other children, but those bites are hardly ever severe. Human bites are capable of transmitting a wide range of dangerous diseases, including **hepatitis B**, **syphilis**, and **tuberculosis**.

Human bites fall into two categories: occlusional (true) bites and clenched-fist injuries. Occlusional bites present a lower risk of infection. Clenched-fist injuries, which are very infectious and can permanently damage the hand, usually result from a fist hitting teeth during a fight. People often wait before seeking treatment for a clenched-fist injury, with the result that about half of such injuries are infected by the time they are seen by a medical professional.

Spiders

As a rule, people rarely see a black widow bite, nor do they feel the bite as it occurs. The first (and possibly

WWW.BOOKBAZ.IR

KEY TERMS

Anaphylaxis—Also called anaphylactic shock; a severe allergic reaction characterized by airway constriction, tissue swelling, and lowered blood pressure.

Debridement—Removal of dead and damaged tissue.

Hepatitis—A disease that causes inflammation of the liver and serious liver damage.

only) evidence that a person has been bitten may be a mild swelling of the injured area and two red puncture marks. Within a short time, some victims begin to experience severe **muscle cramps** and rigidity of the abdominal muscles. Other possible symptoms include excessive sweating, nausea, **vomiting**, headaches, and vertigo, as well as breathing, vision, and speech problems.

A brown spider's bite can lead to necrotic arachnidism, in which the tissue in an area of up to several inches around the bite becomes necrotic (dies), producing an open sore that can take months or years to disappear. In most cases, the bite simply produces a hard, painful, itchy, and discolored area that heals without treatment in 2–3 days. The bite may be accompanied by a **fever**, chills, **edema** (an accumulation of excess tissue fluid), **nausea and vomiting**, **dizziness**, muscle and joint pain, and a rash.

Bees and wasps

The familiar symptoms of bee and wasp stings include pain, redness, swelling, and itchiness in the area of the sting. Multiple stings can have much more severe consequences, such as **anaphylaxis**, a life-threatening allergic reaction that occurs in hypersensitive persons.

Snakes

Venomous pit viper bites usually begin to swell within 10 minutes and sometimes are painful. Other symptoms include skin blisters and discoloration, weakness, sweating, nausea, faintness, dizziness, bruising, and tender lymph nodes. Severe **poisoning** can lead to tingling in the scalp, fingers, and toes; muscle contractions; an elevated heart rate; rapid breathing; large drops in body temperature and blood pressure; vomiting of blood; and **coma**.

Many pit viper and coral snake bites (20–60%) fail to poison (envenomate) their victim, or introduce only a small amount of venom into the victim's body. The **wounds**, however, can still become infected by the harmful microorganisms that snakes carry in their mouths.

Coral snake bites are painful but may be hard to see. One to seven hours after the bite, a bitten person begins to experience the effects of the venom, which include tingling at the wound site, weakness, nausea, vomiting, excessive salivation, and irrational behavior. Major nerves of the body can become paralyzed for 6–14 days, causing double vision, difficulty swallowing and speaking, **respiratory failure**, and other problems. Six to eight weeks may be needed before normal muscular strength is regained.

Jellyfish

Jellyfish venom is delivered by barbs called nematocysts, which are located on the creature's tentacles and penetrate the skin of people who brush up against them. Instantly, painful and itchy red lesions usually result. The pain can continue up to 48 hours. Severe cases may lead to skin **necrosis**, **muscle spasms and cramps**, vomiting, nausea, **diarrhea**, headaches, excessive sweating, and other symptoms. In rare instances, cardiorespiratory failure may occur.

Stingrays

Tail spines are the delivery mechanism for stingray venom. Deep puncture wounds result that can cause an infection if pieces of spine become embedded in the wound. A typical stingray injury scenario involves a person who inadvertently steps on a resting stingray and is lashed in the ankle by its tail. Stingray venom produces immediate, excruciating pain that lasts several hours. Sometimes the victim has a severe reaction, including vomiting, diarrhea, hemorrhage (bleeding), a drop in blood pressure, and cardiac arrhythmia (disordered heart beat).

Diagnosis

Dogs

Gathering information on the circumstances of a dog attack is a crucial part of treatment. Medical professionals need to know when the attack occurred (the chances of infection increase dramatically if the wound has been left untreated more than eight hours) and what led to the attack (unprovoked attacks are more likely to be associated with rabies). A person's general health must also be assessed, including the

tetanus immunization history (if any), as well as information concerning possible **allergies** to medication and pre-existing health problems that may increase the risk of infection.

A **physical examination** requires careful scrutiny of the wound, with special attention to possible bone, joint, ligament, muscle, tendon, nerve, or blood vessel damage caused by deep punctures or severe crush injuries. Serious hand injuries should be evaluated by a specialized surgeon. Laboratory tests for identifying the microorganisms in bite wounds are performed if infection is present. X rays and other diagnostic procedures may be necessary.

Cats

The diagnostic procedures used for dog bites also apply to cat bites.

Humans

Testing the blood of a person who has been bitten for immunity to hepatitis B and other diseases is always necessary after a human bite. Ideally, the biter should be tested for the presence of transmissible disease. Clenched-fist injuries often require evaluation by a hand surgeon or orthopedist. Because many people deny having been in a fight, medical professionals usually consider lacerations over the fourth and fifth knuckles—the typical result of a clenched-fist injury—to be evidence of a bite wound. Medical professionals also look for indications of spousal or child **abuse** when evaluating human bites.

Spiders

Because bites from widow spiders and brown spiders require different treatments, capturing and identifying the spider helps to establish diagnosis.

Snakes

Diagnosis relies on a physical examination of the victim, information about the circumstances of the bite, and a look at the snake itself (if it can safely be killed and brought in for identification). Blood tests and **urinalysis** supply important data on the victim's condition. Chest x rays and **electrocardiography** (a procedure for measuring heart activity) may also be necessary.

Treatment

Dogs

Minor dog bites can be treated at home. The American Academy of Family Physicians recommends gently washing the wound with soap and water and then applying pressure to the injured area with a clean towel to stop the bleeding. The next step is to apply antibiotic ointment and a sterile bandage to the wound. To reduce swelling and fend off infection, ice should be applied and the injured area kept elevated above the level of the heart. The wound should be cleaned and covered with ointment twice a day until it heals.

Any dog bite that does not stop bleeding after 15 minutes of pressure must be seen by a medical professional. The same is true for bites that are deep or gaping; bites to the head, hands, or feet; and bites that may have broken a bone, damaged nerves, or caused a major injury of another kind. Bite victims must watch for infection. A fever is one sign of infection, as are redness, swelling, warmth, increased tenderness, and pus at the wound site. People who are diabetic, who have AIDS or cancer, individuals who have not had a tetanus shot in five years, and anyone else who has a medical problem that can increase susceptibility to infection should seek medical treatment no matter how minor the bite appears.

Medical treatment of dog bites involves washing (irrigating) the wound with an anti-infective solution. Removal of dead and damaged tissue (**debridement**) under local, regional, or general anesthetic may be required after the wound has been washed, and any person whose tetanus shots are not up to date should receive a booster injection. Some wounds are left open and allowed to heal on their own, while others require stitches (stitching may be delayed a few days if infection is a concern). Many emergency departments prescribe **antibiotics** for all people with dog bites, but some researchers suggest that antibiotics usually are unnecessary and should be limited to those whose injuries or other health problems make them likely candidates for infection. A follow-up visit after one or two days is generally required for anyone who has received bite treatment.

Cats

Because of the high risk of infection, people who are bitten by a cat should always see a doctor. Cat scratches do not require professional medical treatment unless the wound appears infected or the scratched person has a weakened immune system.

Medical treatment for cat bites generally follows the procedures used for dog bites. Experts advise that cat-bite wounds should be left open to prevent infection. Persons who have been bitten by cats usually receive antibiotics as a preventive measure.

WWW.BOOKBAZ.IR

Humans

Human bites should always be examined by a doctor. Such bites are normally treated with antibiotics and left open because of the high risk of infection. Routine use of antibiotics for human bites may not be necessary, as physicians try to minimize overuse of antibiotics. Superficial wounds in low-risk areas may no longer need antibiotic treatment, but more serious human bites to high-risk areas such as the hands should be treated with antibiotics to prevent serious infection. A person who has been bitten may require immunization against hepatitis B and other diseases. Persons who are being treated for a clenched-fist injury require a daily follow-up examination for 3–5 days.

Spiders

No spider bite should be ignored. The antidote for severe widow spider bites is a substance called antivenin, which contains antibodies taken from the blood serum of horses injected with spider venom. Doctors **exercise** caution in using antivenin because it can trigger anaphylactic **shock**, a potentially deadly allergic reaction, and **serum sickness**, an inflammatory response that can give rise to joint pain, a fever, **rashes**, and other unpleasant, though rarely serious, consequences.

An antivenin for brown spider bites exists as well, but it is in limited distribution. The drug dapsone, used to treat **leprosy**, can sometimes stop the tissue death associated with a brown spider bite. Necrotic areas may need debridement and skin grafts. Pain medications, **antihistamines**, antibiotics, and tetanus shots are a few of the other treatments that are sometimes necessary after a bite from a brown spider or widow spider.

Bees and wasps

Most stings can be treated at home. A stinger that is stuck in the skin can be scraped off with a blade, fingernail, credit card, or piece of paper (using tweezers may push more venom out of the venom sac and into the wound). The area should be cleaned and covered with an ice pack. **Aspirin** and other pain medications, oral antihistamines, and calamine lotion are good for treating minor symptoms. Putting meat tenderizer on the wound has no effect.

People who have been stung and experience an allergic reaction, or who are at risk due to their medical history, require immediate medical attention. The danger signs, which usually begin 10 minutes after an individual is stung (although possibly not for several hours), include nausea, faintness, chest pain, abdominal cramps, diarrhea, and difficulty swallowing or breathing.

Snakes

Although most snakes are not venomous, any snakebite should immediately be examined at a hospital. While waiting for emergency help to arrive, the victim should wash the wound site with soap and water, and then keep the injured area still and at a level lower than the heart. Ice should never be used on the wound site nor should attempts be made to suck out the venom. Making a cut at the wound site is also dangerous. It is important to stay calm and wait for emergency medical aid if it can arrive quickly. Otherwise, the victim should proceed directly to a hospital.

When the victim arrives at a hospital, the medical staff must determine whether the bite was inflicted by a venomous snake and, if so, whether envenomation occurred and how much venom the person has received. Patients may develop low blood pressure, abnormal blood clotting, or severe pain, all of which require aggressive treatment. Fortunately, the effects of some snakebites can be counteracted with antivenin. Minor rattlesnake envenomations can be successfully treated without antivenin, as can copperhead and water moccasin bites. Coral snake envenomations and the more dangerous rattlesnake envenomations require antivenin, sometimes in large amounts. Other treatment measures include antibiotics to prevent infection and a tetanus booster injection.

Jellyfish

Vinegar and other acidic substances are used to neutralize jellyfish nematocysts still clinging to the skin, which are then scraped off. Anesthetic ointments, antihistamine creams, and steroid lotions applied to the skin are sometimes beneficial. Other measures may be necessary to counter the many harmful effects of jellyfish stings, which, if severe, require emergency medical care.

Stingrays

Stingray wounds should be washed with saltwater and then soaked in very hot water for 30–90 minutes to neutralize the venom. Afterwards, the wound should be examined by a doctor to ensure that no pieces of spine remain.

Alternatives

Arthropods

Several alternative self-care approaches are used to treat minor bee, wasp, and other arthropod stings, including **aromatherapy**, **Ayurvedic medicine**, **flower remedies**, herbs, homeopathy, and nutritional therapy.

Prognosis

Mammals

Prompt treatment and recognizing that even apparently minor bites can have serious consequences are the keys to a good outcome after a mammal bite. Infected bites can be fatal if neglected. Surgery and hospitalization may be needed for severe bites.

Spiders

Even without treatment, adults usually recover from black widow bites after 2–3 days. Those most at risk of dying are very young children, the elderly, and people with high blood pressure. In the case of brown spider bites, the risk of death is greatest for children, although rare.

Bees and wasps

The pain and other symptoms of a bee or wasp sting normally fade away after a few hours. People who are allergic to such stings can experience severe and occasionally fatal anaphylaxis.

Snakes

A snakebite victim's chances of survival are excellent if medical aid is obtained in time. Some bites result in **amputation**, permanent deformity, or loss of function in the injured area.

Stingrays

Stingray venom rarely leads to death in humans.

Prevention

Dogs

The risk of a dog bite injury can be reduced by avoiding sick or stray dogs, staying away from dogfights (people often get bitten when they try to separate the animals), and not behaving in ways that might provoke or upset dogs, such as wrestling with them or bothering them while they are sleeping, eating, or looking after their puppies. Special precautions need to be taken around infants and young children, who must never be left alone with a dog. Pit bulls, Rottweilers, and German shepherds are responsible for nearly half of all fatal dog attacks in the United States and are potentially dangerous pets in households where children live or visit. For all breeds of dog, obedience training and spaying or neutering lessen the chances of aggressive behavior.

Cats

Prevention involves warning children to stay away from strange cats and to avoid rough play and other behavior that can anger cats and cause them to bite.

Spiders

Common-sense precautions include clearing webs out of garages, outhouses, and other places favored by venomous spiders; keeping one's hands away from places where spiders may be lurking; and checking clothing, shoes, and sleeping areas when camping or vacationing.

Bees and wasps

When possible, it is advised to avoid the nests of bees and wasps and to not eat sweet food or wear bright clothing, perfumes, or cosmetics that attract bees and wasps.

Emergency medical kits containing self-administrable epinephrine (Epi-pen) to counter anaphylactic shock are available for people allergic to bee or wasp stings and should be carried by them at all times. People who suspect they are allergic should consult an allergist about shots that can reduce reactions to bee and wasp venom.

Snakes

Snakes should not be kept as pets. Measures such as mowing the lawn, keeping hedges trimmed, and removing brush from the yard discourages snakes from living close to human dwellings. Tongs should be used to move brush, lumber, and firewood, to avoid exposing one's hands to snakes that might be lying underneath. Similarly, golfers should never use their hands to retrieve golf balls from a water hole, since snakes can be hiding in the rocks and weeds. Caution is also necessary when walking through weedy or grassy areas. Children should be prevented from playing in weedy, vacant lots and other places where snakes may live. Leather boots and long pants offer hikers and campers some protection from bites. Approaching a snake, even a dead one, can be dangerous, for the venom of recently killed snakes may still be active.

Jellyfish

Prevention of jellyfish stings includes obeying posted warning signs at the beach. Jellyfish tentacles may be transparent and up to 120 ft (36.5 m) long; therefore, great caution must be exercised whenever a jellyfish is sighted nearby. An over-the-counter cream

WWW.BOOKBAZ.IR

tested at the Stanford University in 2004 was shown to prevent jellyfish stings.

Stingrays

Shuffling while walking through shallow areas that may be inhabited by stingrays will disturb the water, causing the animal to move before it can be stepped on.

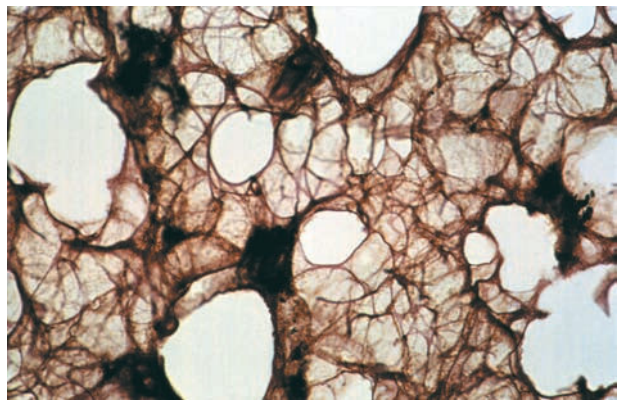
Black death *see* **Plague**

Black lung disease

Definition

Black lung disease is the common name for coal workers' pneumoconiosis (CWP) or anthracosis, a lung disease of older workers in the coal industry caused by inhalation, over many years, of small amounts of coal dust.



A light micrograph of a human lung containing particles of inhaled coal dust (anthracosis). The black masses shown are groups of coal dust particles. *(Astrid & Hanns-Frieder Michler/ Photo Researchers, Inc.)*

Description

The risk of having black lung disease is directly related to the amount of dust inhaled over the years; the disease typically affects workers over age 50. Its common name comes from the fact that the inhalation of heavy deposits of coal dust makes miners lungs look black instead of a healthy pink. Although people who live in cities often have some black deposits in their lungs from polluted air, coal miners have much more extensive deposits.

In the years since the federal government has regulated dust levels in coal mines, the number of cases of black lung disease has fallen sharply. Since the Federal Coal Mine Health and Safety Act of 1969, average dust levels have fallen from 8.0 mg per cubic meter to the current standard of 2.0 mg per cubic meter. The 1969 law also set up a black lung disability benefits program to compensate coal miners who have been disabled by on-the-job dust exposure.

Despite the technology available to control the hazard, however, miners still run the risk of developing this lung disease. The risk is much lower in the early 2000s, however; fewer than 10% of coal miners have any x ray evidence of coal dust deposits. When there is such evidence, it often shows up as only small black spots less than 0.4 in. (1 cm) in diameter, and may have been caused by **smoking** rather than coal dust. This condition is called "simple CWP" and does not lead to symptoms or disability.

Causes and symptoms

Since the particles of fine coal dust, which a miner breathes when he is in the mines, cannot be destroyed within the lungs or removed from them, they build up. Eventually, this build up causes thickening and

scarring, making the lungs less efficient in supplying oxygen to the blood.

The primary symptom of the disease is **shortness of breath**, which gradually gets worse as the disease progresses. In severe cases, the patient may develop **cor pulmonale**, an enlargement and strain of the right side of the heart caused by chronic lung disease. This may eventually cause right-sided **heart failure**.

Some patients develop **emphysema** (a disease in which the tiny air sacs in the lungs become damaged, leading to shortness of breath, and respiratory and heart failure) as a complication of black lung disease. Others develop a severe type of black lung disease called progressive massive fibrosis, in which damage continues in the upper parts of the lungs even after exposure to the dust has ended. Scientists are not sure what causes this serious complication. Some think that it may be due to the breathing of a mixture of coal and silica dust that is found in certain mines. Silica is far more likely to lead to scarring than coal dust alone.

Diagnosis

Black lung disease can be diagnosed by checking a patient's history for exposure to coal dust, followed by a chest x ray to discover if the characteristic spots in the lungs caused by coal dust are present. A pulmonary function test may aid in diagnosis.

X rays can detect black lung disease before it causes any symptoms. If exposure to the dust is stopped at that point, progression of the disease may be prevented.

Treatment

There is no treatment or cure for this condition, although it is possible to treat complications such as lung infections and cor pulmonale. Further exposure to coal dust must be stopped.

Prognosis

Those miners with simple CWP can lead a normal life. However, patients who develop black lung disease at an early age, or who have progressive massive fibrosis, have a higher risk of premature death.

Prevention

The only way to prevent black lung disease is to avoid long-term exposure to coal dust. Coal mines may help prevent the condition by lowering coal dust levels and providing protective clothes to coal miners.

Carol A. Turkington

Bladder calculi *see* **Bladder stones**

Bladder cancer

Definition

Bladder cancer is a disease in which the cells lining the urinary bladder lose the ability to regulate their growth and start dividing uncontrollably. This abnormal growth results in a mass of cells that form a tumor. The most common type of bladder cancer diagnosed in the United States is urothelial bladder cancer, which in the past was classified as transitional cell carcinoma of the bladder.

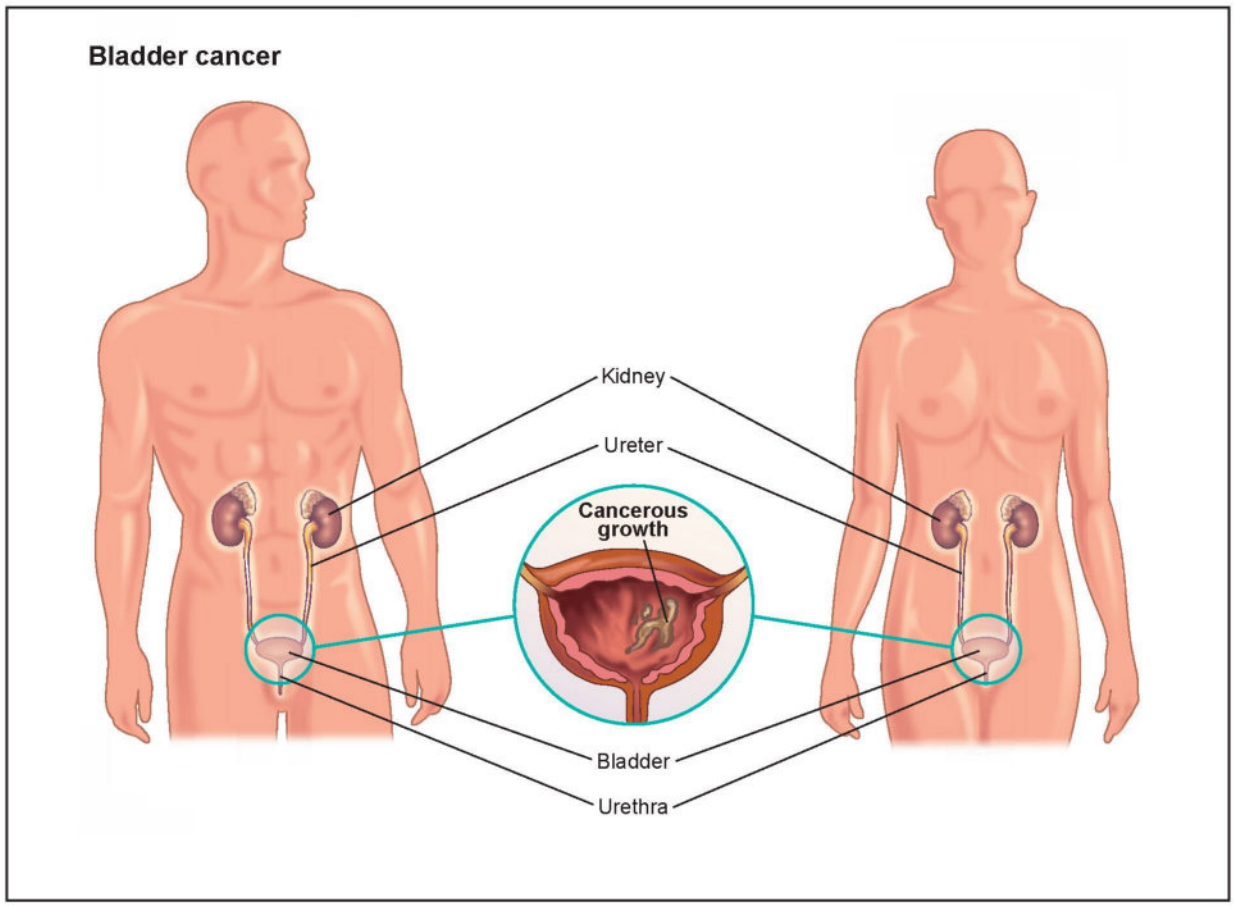
Demographics

Bladder cancer is the fourth most commonly diagnosed cancer in men and the tenth most common cancer diagnosed in women in the United States. In 2009, the American Cancer Society (ACS) estimated that approximately 70,980 new cases of bladder cancer would be diagnosed (about 52,810 men and 18,170 women), causing approximately 14,330 deaths. The mortality rate for bladder cancer has declined since the 1990s. Greater than 90% of cases are diagnosed in individuals 55 years of age and older.

The rates for bladder cancer in men of African descent and Hispanic men are similar and are approximately one-half of the rate among white non-Hispanic men. The lowest rate of bladder cancer occurs in the Asian population. Among women, the highest rates also occur in white non-Hispanic females and are approximately twice the rate for Hispanics. Women of African descent have higher rates of bladder cancer than Hispanic women. Although blacks are diagnosed with bladder cancer less frequently than whites, their cancers are often diagnosed in later stages resulting in a poorer overall prognosis.

Approximately 75% of patients are diagnosed with bladder cancer that is confined to the bladder. Only 3% are diagnosed with bladder cancer that has spread to distant sites in the body at the time of diagnosis.

WWW.BOOKBAZ.IR



The urinary systems of a man and a woman, illustrating bladder cancer on the inner lining of the bladder. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

The urinary bladder is a hollow muscular organ that stores urine from the kidneys until it is excreted out of the body. Two tubes called the ureters bring the urine from the kidneys to the bladder. The urethra carries the urine from the bladder to the outside of the body.

Bladder cancer has a very high rate of recurrence. Even after superficial tumors are completely removed, there is a 75% chance new tumors will develop in other areas of the bladder. Hence, patients need frequent and thorough follow-up care.

Risk factors

Smoking is considered the greatest risk factor for this type of cancer and by some estimates accounts for about 50% of all bladder cancers. Workers who are exposed to certain chemicals used in the dye industry and in the rubber, leather, textile, and paint industries are believed to be at a higher risk for bladder cancer. The disease also is three times more common in men than in women; Caucasians also are at an increased risk. The risk of bladder cancer increases with age. Most cases are found in people who are 50–70 years old.

Frequent urinary infections, kidney and **bladder stones**, and other conditions that cause long-term irritation to the bladder may increase the risk of getting bladder cancer. For example, individuals with spinal cord injuries requiring in-dwelling urinary catheters have a 16 to 20 times increased risk of developing bladder cancer. A past history of tumors in the bladder also could increase one's risk of getting other tumors.

Patients who have been previously treated with the cancer **chemotherapy** drug cyclophosphamide are at increased risk as are those who have been previously treated with radiation to the pelvis.

Several genetic mutations are associated with bladder cancer. Although heredity is not typically linked with the development of this type of cancer, familial clusters of bladder cancer have been identified.

Causes and symptoms

The exact cause of bladder cancer is not known, but smokers are twice as likely as nonsmokers to get the disease.

One of the first warning signals of bladder cancer is blood in the urine, which is reported by 80% of patients. This change in the urine is not typically associated with any **pain**. Sometimes, there is enough blood to change the color of the urine to a yellow-red or a dark red. At other times, the color of the urine appears normal but chemical testing of the urine reveals the presence of blood cells. A change in bladder habits such as painful urination, increased frequency of urination and a feeling of needing to urinate but not being able to do so are some of the signs of possible bladder cancer. All of these symptoms may be caused by conditions other than cancer, but it is important to see a doctor and have the symptoms evaluated. When detected early and treated appropriately, patients have a very good chance of being cured completely.

Symptoms associated with advanced bladder cancer may include flank, back, and/or pelvic pain and **edema** in the lower extremities.

Diagnosis

Examination

If a doctor has any reason to suspect bladder cancer, several tests can help find out if the disease is present. As a first step, a complete medical history will be taken to check for any risk factors. A thorough **physical examination** will be conducted to assess all the signs and symptoms.

Tests

Laboratory testing of a urine sample helps to rule out the presence of a bacterial infection. In a urine **cytology** test, the urine is examined under a microscope to look for any abnormal or cancerous cells.

Procedures

A catheter (tube) is sometimes advanced into the bladder through the urethra, and a salt solution is passed through it to wash the bladder. The solution is collected and examined under a microscope to check for the presence of cancerous cells.

Another procedure, known as the intravenous pyelogram (IVP), is an x-ray examination that is done after a dye is injected into the bloodstream through a vein in the arm. The dye travels through the bloodstream and then reaches the kidneys to be excreted. It clearly outlines the kidneys, ureters, bladder, and urethra. Multiple x rays are taken to detect any abnormality in the lining of these organs. In addition to the IVP, a renal **ultrasound** may be used in the diagnosis of bladder cancer.

A procedure known as a **cystoscopy** may be used to view the inside of the bladder. A thin, hollow, lighted tube is introduced into the bladder through the urethra. If any suspicious looking masses are seen, a small piece of the tissue can be removed from it using a pair of biopsy forceps. The tissue is then examined microscopically to verify if cancer is present, and if so, to identify the type of cancer.

If cancer is detected and there is evidence to indicate that it has metastasized (spread) to distant sites in the body, imaging tests such as chest x rays, **computed tomography scans** (CT), and **magnetic resonance imaging** (MRI) may be done to determine which organs are affected. Bladder cancer generally tends to spread to the lungs, liver, and bone.

Treatment

Treatment for bladder cancer depends on the stage of the tumor; specifically, whether the tumor has invaded the muscle wall of the bladder. The patient's medical history, overall health status, and personal preferences are taken into account when deciding on an appropriate treatment plan.

Traditional

Cystectomy, surgical removal of the bladder, may be used to treat cases of non-invasive and muscle-wall invasive cancers. In non-muscle invasive disease cystectomy may be performed if the tumor is an aggressive type that tends to recur despite treatment with BCG. A 90% survival rate can be attained in this group of patients if the cystectomy is done prior to progression of the tumor to the muscle wall. The 5-year survival rate after cystectomy drops by 30–40% once the muscle wall has been invaded by tumor. Surgery may also be recommended for patients with large superficial tumors that cannot be surgically removed, those with prostatic urethral involvement, and for patients who did not respond to BCG therapy.

In patients with muscle-invasive disease, surgery is done to remove the bladder, prostate, and pelvic lymph nodes in men. In women, the bladder, urethra, uterus, ovaries, anterior vaginal wall, and pelvic lymph nodes may be removed.

WWW.BOOKBAZ.IR

KEY TERMS

Cystectomy—Surgical removal of the bladder.

Cystoscopy—A diagnostic procedure that uses a cystoscope to look inside the bladder and to collect samples of urine and tissue.

Immunotherapy—A form of treatment that targets specific cells in the body's immune system to disrupt the growth of a cancer.

Urostomy—A surgical opening (a stoma) created to divert urine to outside the body for collection once the bladder has been removed.

If the entire urinary bladder is removed, an alternate place must be created for the urine to be stored before it is excreted out of the body. To do this, a piece of intestine is converted into a small bag and attached to the ureters. This is then connected to an opening (stoma) that is made in the abdominal wall. The procedure is called a urostomy or a urinary diversion. In some urostomy procedures, the urine from the intestinal sac is routed into a bag that is placed over the stoma in the abdominal wall. The bag is hidden by the clothing and has to be emptied occasionally by the patient. In a different procedure, the urine is collected in the intestinal sac, but there is no bag on the outside of the abdomen. The intestinal sac has to be emptied by the patient, by placing a drainage tube through the stoma.

External beam **radiation therapy** as a primary therapy is not as effective as cystectomy in the treatment of bladder cancer. For disease confined to the bladder, the 5-year survival rate after cystectomy is 90% compared to a 5-year survival rate of 20–40% for patients treated with external beam radiation.

Drugs

Modalities used to treat non-muscle invasive bladder cancer include instilling Bacillus Calmette-Guerin (BCG) immunotherapy directly into the bladder and/or instilling chemotherapy agents such as Thiotepa, mitomycin-C, doxorubicin, and/or epirubicin directly into the bladder. Recommendations for the treatment of muscle-invasive bladder cancer include administration of adjuvant and neoadjuvant chemotherapy. Common chemotherapy agents used are methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC regimen). Metastatic bladder cancer can also be treated with the MVAC chemotherapy regimen. A newer regimen that uses the chemotherapy drugs gemcitabine and cisplatin (GC) has proved to be just as effective as the MVAC regimen in the treatment of metastatic bladder cancer and is now considered a first-line treatment option.

Prognosis

When detected in early stages, the prognosis for those with bladder cancer is excellent. At least 90% of people diagnosed with non-muscle invasive bladder cancer survive five years or more after initial diagnosis. However, if the disease has spread to the nearby tissues, the survival rate drops. Once the cancer has metastasized to distant organs such as the lung and liver, only 5% of patients survive two years or more. As newer treatment methods are developed, some prognoses improve.

Non-muscle invasive bladder cancers have a high rate of recurrence and progression. Careful follow-up and surveillance is of critical importance and includes cystoscopy and bladder wash cytology every three months for two years, then every six months for two years, followed by a minimum of once yearly.

Prevention

Since the exact causes of bladder cancer are not known, there is no certain way to prevent it. Avoiding risk factors whenever possible is the best alternative.

Since smoking doubles one's risk of getting bladder cancer, avoiding tobacco may prevent at least half the deaths that result from bladder cancer. Taking appropriate safety precautions when working with organic cancer-causing chemicals is another way of preventing the disease.

If a person has had a history of bladder cancer, or has been exposed to cancer-causing chemicals, he or she is considered to be at an increased risk of getting bladder cancer. Similarly, **kidney stones**, frequent urinary infections, and other conditions that cause long-term irritation to the bladder also increase the chance of getting the disease.

Bladder resection *see* **Transurethral bladder resection**

Bladder stones

Definition

Bladder stones are crystalline masses that form from the **minerals** and proteins that naturally occur in urine. These types of stones are much less common than **kidney stones**.

Description

Bladder stones can form anywhere in the urinary tract before depositing in the bladder. They begin as tiny granules about the size of a grain of sand, but they can grow to more than an inch in diameter. These stones can block the flow of urine causing **pain** and difficulty with urination. They can also scratch the bladder wall, which may lead to bleeding or infection.

Causes and symptoms

While the exact causes of the formation of bladder stones are not completely understood, bladder stones usually occur because of **urinary tract infection** (UTI), obstruction of the urinary tract, enlargement of the prostate gland in men, or the presence of foreign bodies in the urinary tract. Diet and the amount of fluid intake also appear to be important factors in the development of bladder stones.

Ninety-five percent of all bladder stones occur in men, most of whom have an **enlarged prostate** gland or a UTI. These stones are rarely seen in children or in African Americans. People with **gout** may develop bladder stones composed almost entirely of uric acid.

The symptoms of bladder stones may become evident when the wall of the bladder is scratched or when the urinary tract becomes obstructed by the stone. These symptoms include:

- abnormally dark colored urine
- blood in the urine
- difficulty urinating
- frequent urge to urinate
- lower abdominal pain
- pain or discomfort in the penis

Some people with bladder stones also may experience an inability to control urination (**urinary incontinence**).

Diagnosis

The diagnosis of bladder stones is usually made after a **physical examination**, which may include a **rectal examination** to check for enlargement of the prostate gland. Urine tests are then used to determine if there is blood or indications of an UTI in the urine. If bladder stones are suspected, bladder or pelvic x rays may be ordered. Stones that are large enough to cause problems with urinary function are almost always detectable by x ray.

Treatment

Many bladder stones can be passed out of the body in the urine. People with small bladder stones will be asked to increase their fluid intakes to at least six to eight eight-ounce glasses of water per day to increase urinary output. If the stones do not pass after two weeks, or if the patient's symptoms become worse, further medical treatment may be required.

A large bladder stone, or small stone that the patient cannot pass in the urine, may be broken up

WWW.BOOKBAZ.IR

into smaller stones using **ultrasound** (shock waves). These smaller stones may then pass in the urine. Stones that cannot be broken into pieces by these methods, or that the patient cannot pass, may have to be surgically removed.

Alternatives

Traditional herbal remedies for bladder stones include celery seed and horsetail. Also, because incomplete bladder emptying may cause bladder stones, many patients may benefit from methods and remedies aimed at improving overall bladder function. These include Kegel exercises, which are used to strengthen the muscles involved in urination; herbal supplements (cornsilk, hydrangea, juniper berries, parsley, and uva ursi) used to increase urine flow and flush out sediment from the bladder; and the consumption of cranberry juice and/or fresh, unsweetened lemon juice. Cranberry juice helps to control urinary tract infection and contains a chemical that coats the walls of the bladder, making them more resistant to infection. Lemon juice helps to flush out the urinary system.

Prognosis

Most bladder stones can be, and are, passed out of the body in the urine without any permanent damage to the bladder or the rest of the urinary tract. However, most bladder stones arise from an underlying medical condition. Therefore, if this medical condition is not corrected approximately half of all patients will experience a recurrence of bladder stones within five years.

Prevention

Bladder stones may, in some cases, be prevented by the patient receiving prompt medical treatment for an enlarged prostate gland or UTI. The consumption of at least six to eight eight-ounce glasses of water per day and/or the regular consumption of cranberry juice may help to prevent recurrences of bladder stones.

Bladder training

Definition

Bladder training is a behavioral modification treatment technique for **urinary incontinence** that involves placing a patient on a toileting schedule. The time interval between urination is gradually increased in order to train the patient to remain continent.

Purpose

Bladder training is used to treat urinary urge incontinence. Urge incontinence occurs when an individual feels a sudden need to urinate and cannot control the urge to do so and, as a consequence, involuntarily loses urine before making it to the toilet.

Precautions

Incontinence may be controlled through a number of invasive and non-invasive treatment options, including Kegel exercises, **biofeedback**, bladder training, medication, insertable incontinence devices, and surgery. Each patient should undergo a full diagnostic work-up to determine the type and cause of the incontinence in order to determine the best course of treatment.

Description

Bladder training may be prescribed and implemented by a general physician, urologist, or urogynecologist. A urination schedule is created for the patient. The schedule typically starts out with fairly short intervals between bathroom breaks (e.g., an hour). As soon as the patient is able to consistently remain continent for several days at a certain toileting time interval, the time span is increased. Bladder training continues until the patient regularly achieves continence at a time interval he/she feels comfortable with.

Preparation

A complete evaluation to determine the cause of urinary incontinence is critical to proper treatment. A thorough medical history and **physical examination** should be performed on patients considering bladder training. Diagnostic testing may include x rays, **ultrasound**, urine tests, and a physical examination of the pelvis. It may include a series of exams called urodynamic testing that measure bladder pressure and capacity and the urinary flow. The patient may also be asked to keep a diary of their urination output and frequency and episodes of incontinence over a period of several days or a week.

Risks

Bladder training may not be successful in all patients with urge incontinence. Patients who demonstrate a strong desire to control their continence and are committed to sticking with a training program tend to have the most success with bladder training.

Results

Patients who undergo successful bladder training gain complete or improved control over their urination. In some cases, additional alternate treatment such as biofeedback or pelvic muscle exercises may be recommended to supplement the progress made with bladder training.

Paula Anne Ford-Martin

Blastomyces dermatitidis see **Blastomycosis**

Blastomycosis

Definition

Blastomycosis is an infection caused by inhaling microscopic particles (spores) produced by the fungus *Blastomyces dermatitidis*. Blastomycosis may be limited to the lungs or also involve the skin and bones. In its most severe form, the infection can spread throughout the body and involve many organ systems (systemic).

Description

Blastomycosis is a fungal infection caused by *Blastomyces dermatitidis*. Although primarily an airborne disease, farmers and gardeners may become infected from contact with spores in the soil through cuts and scrapes. The fungus that causes the disease is found in moist soil and wood in the southeastern United States, the Mississippi River valley, southern Canada, and Central America. Blastomycosis is also called Gilchrist's disease, Chicago disease, or North American blastomycosis. Another South and Central American disease, paracoccidioidomycosis, is sometimes called **South American blastomycosis**, but despite the similar name, this disease is substantially different from North American blastomycosis. Canine blastomycosis, a common dog disease, is caused by the same fungus that infects humans. However, people do not get this disease from their dogs except only very rarely through dog bites.

Blastomycosis is usually attributed to contact with yeast-like fungi. *(Custom Medical Stock Photo, Inc.)*

Blastomycosis is a rare disease infecting only about 4 in every 100,000 people. It is at least six times more common in men than in women and tends to more often infect children and individuals in the 30–50-year- old age group. People who have **diabetes mellitus** or who are taking drugs that suppress the immune system (immunocompromised) are more likely to develop blastomycosis. Although people with **AIDS** can get blastomycosis because of their weakened immune system, blastomycosis has not been one of the more common **fungal infections** associated with AIDS.

Causes and symptoms

Once inhaled, the spores of *B. dermatitidis* can lodge in the lungs and cause a localized inflammation. This is known as primary pulmonary blastomycosis. The disease does not spread from one person to another. In the early stages, symptoms may include a dry **cough**, **fever**, heavy sweating, **fatigue**, and a general feeling of ill health. In approximately 25% of blastomycosis cases, only the lungs are affected. As the disease progresses, small lesions form in the lungs causing the air sacs deep within the lungs (alveoli) to break down and form small cavities.

In another 35%, the disease involves both the lungs and the skin. Bumps develop on the skin,

WWW.BOOKBAZ.IR

gradually becoming small, white, crusted blisters filled with pus. The blisters break open, creating abscesses that do not heal. Approximately 19% of infected people have skin sores without infection in the lungs.

The remaining approximately 20% of the infected population has blastomycosis that has spread or disseminated to other systems of the body. Symptoms may include **pain** and lesions on one or more bones, the male genitalia, and/or parts of the central nervous system. The liver, spleen, lymph nodes, heart, adrenal glands, and digestive system may also be infected.

Diagnosis

A positive diagnosis of blastomycosis is made when the fungus *B. dermatitidis* is identified by direct microscopic examination of body fluids such as sputum and prostate fluid or in tissue samples (biopsies) from the lung or skin. Another way to diagnose blastomycosis is to culture and isolate the fungus from a sample of sputum. Chest x rays are used to assess lung damage, but alone cannot lead to a definitive diagnosis of blastomycosis because any damage caused by other diseases, such as by **pneumonia** or **tuberculosis**, may appear on the x ray. Because its symptoms vary widely, blastomycosis is often misdiagnosed.

Treatment

Blastomycosis must be treated or it will gradually lead to death. Treatment with the fungicidal drug ketoconazole (Nizoral) taken orally is effective in about 75% of patients. Amphotericin B (Fungizone) given intravenously is also very effective, but it has more toxic side effects than ketoconazole. Treatment with amphotericin B usually requires hospitalization, and the patient may also receive other drugs to minimize its side effects.

Alternatives

Alternative treatment for fungal infections focuses on creating an internal environment where the fungus cannot survive. This is accomplished by eating a diet low in dairy products; sugars, including honey and fruit juice; and foods like beer that contain yeast. This is complemented by a diet consisting, in large part, of uncooked and unprocessed foods. Supplements of **vitamins** C, E, A-plus, and B complex may also be useful. *Lactobacillus acidophilus* and *Bifidobacterium* will replenish the good bacteria in the intestines. Some antifungal herbs, like garlic (*Allium sativum*), can be consumed in relatively large doses and for an extended period of time in order to increase effectiveness. A variety of antifungal herbs such as myrrh (*Commiphora molmol*), tea tree oil (*Melaleuca* spp.), citrus seed extract, pau d'arco tea (*Tabebuia impetiginosa*), and garlic may also be applied directly to the infected skin.

Prognosis

Left untreated, blastomycosis gradually leads to death. When treated, however, patients begin to improve within one week and, with intensive treatment, may be cured within several weeks. The highest rate of recovery is among patients who only have **skin lesions**. People with the disseminated form of the disease are least likely to be cured and most likely to suffer a relapse.

Prevention

Because the fungus that causes blastomycosis is airborne and microscopic, the only form of prevention is to avoid visiting areas where it is found in the soil. For many people this is impractical. Since the disease is rare, people who maintain general good health do not need to worry much about infection.

Bleeding disorders *see* **Coagulation disorders**

Bleeding time

Definition

Bleeding time is a crude test of hemostasis (the arrest or stopping of bleeding). It indicates how well platelets interact with blood vessel walls to form **blood clots**.

Purpose

Bleeding time is used most often to detect qualitative defects of platelets, such as Von Willebrand's disease. The test helps identify people who have defects in their platelet function. This is the ability of blood to clot following a wound or **trauma**. Normally, platelets interact with the walls of blood vessels to cause a blood clot. There are many factors in the clotting mechanism, and they are initiated by platelets. The bleeding time test is usually used on patients who have a history of prolonged bleeding after cuts, or who have a family history

of bleeding disorders. Also, the bleeding time test is sometimes performed as a preoperative test to determine a patient's likely bleeding response during and after surgery. However, in patients with no history of bleeding problems, or who are not taking anti-inflammatory drugs, the bleeding time test is not usually necessary.

Precautions

Before administering the test, patients should be questioned about what medications they may be taking. Some medications will adversely affect the results of the bleeding time test. These medications include anticoagulants, **diuretics**, **anticancer drugs**, **sulfonamides**, thiazide, **aspirin** and aspirin-containing preparations, and **nonsteroidal anti-inflammatory drugs**. The test may also be affected by anemia (a deficiency in red blood cells). Since the taking of aspirin or related drugs are the most common cause of prolonged bleeding time, no aspirin should be taken two weeks prior to the test.

Description

There are four methods to perform the bleeding test. The Ivy method is the traditional format for this test. In the Ivy method, a blood pressure cuff is placed on the upper arm and inflated to 40 mM Hg. A lancet or scalpel blade is used to make a stab wound on the underside of the forearm. An automatic, spring-loaded blade device is most commonly used to make a standard-sized cut. The area stabbed is selected so that no superficial or visible veins are cut. These veins, because of their size, may have longer bleeding times, especially in people with bleeding defects. The time from when the stab wound is made until all bleeding has stopped is measured and is called the bleeding time. Every 30 seconds, filter paper or a paper towel is used to draw off the blood. The test is finished when bleeding has stopped completely.

The three other methods of performing the bleeding test are the template, modified template, and Duke methods. The template and modified template methods are variations of the Ivy method. A blood pressure cuff is used and the skin on the forearm prepared as in the Ivy method. A template is placed over the area to be stabbed and two incisions are made in the forearm using the template as a location guide. The main difference between the template and the modified method is the length of the cut made.

For the Duke method, a nick is made in an ear lobe or a fingertip is pricked to cause bleeding. As in the Ivy method, the test is timed from the start of bleeding until bleeding is completely stopped. The disadvantage to the Duke method is that the pressure on the blood veins in the stab area is not constant and the results achieved are less reliable. The advantage to the Duke method is that no scar remains after the test. The other methods may result in a tiny, hairline scar where the wound was made. However, this is largely a cosmetic concern.

Preparation

There is no special preparation required of the patient for this test. The area to be stabbed should be wiped clean with an alcohol pad. The alcohol should be left on the skin long enough for it to kill bacteria at the wound site. The alcohol must be removed before stabbing the arm because alcohol will adversely affect the tests results by inhibiting clotting.

Aftercare

If a prolonged bleeding time is caused by unknown factors or diseases, further testing is required to identify the exact cause of the bleeding problem.

Results

A normal bleeding time for the Ivy method is less than five minutes from the time of the stab until all bleeding from the wound stops. Some texts extend the normal range to eight minutes. Normal values for the template method range up to eight minutes, while for the modified template methods, up to 10 minutes is considered normal. Normal for the Duke method is three minutes.

Abnormal results

A bleeding time that is longer than normal is an abnormal result. The test should be stopped if the patient has not stopped bleeding by 20–30 minutes. Bleeding time is longer when the normal function of platelets is impaired, or there is a lower-than-normal number of platelets in the blood.

A longer-than-normal bleeding time can indicate that one of several defects in hemostasis is present, including severe **thrombocytopenia**, platelet dysfunction, vascular defects, Von Willebrand's disease, or other abnormalities.

Bleeding varices

Definition

Bleeding varices are bleeding, dilated (swollen) veins in the esophagus (gullet), or the upper part of the stomach, caused by liver disease.

Description

Engorged veins are called varices (plural of varix). Varices may occur in the lining of the esophagus (the tube that connects the mouth to the stomach) or in the upper part of the stomach. Such varices are called esophageal varices. These varices are fragile and can bleed easily because veins are not designed to handle high internal pressures.

Causes and symptoms

Liver disease often causes an increase in the blood pressure in the main veins that carry blood from the stomach and intestines to the liver (portal veins). As the pressure in the portal veins increases, the veins of the stomach and esophagus swell, until they eventually become varices. Bleeding varices are a life-threatening complication of this increase in blood pressure (portal hypertension). The most common cause of bleeding varices is cirrhosis of the liver caused by chronic alcohol abuse or hepatitis. Bleeding varices occur in approximately one in every 10,000 people.

Symptoms of bleeding varices include:

- vomiting blood, sometimes in massive amounts
- black, tarry stools
- decreased urine output
- excessive thirst
- nausea
- vomiting

If bleeding from the varices is severe, a patient may go into shock from the loss of blood, characterized by pallor, a rapid and weak pulse, rapid and shallow respiration, and lowered systemic blood pressure.

Diagnosis

Bleeding varices may be suspected in a patient who has any of the above-mentioned symptoms, and who has either been diagnosed with cirrhosis of the liver or who has a history of prolonged alcohol abuse. The definitive diagnosis is established via a specialized type of endoscopy, namely, esophagogastroduodenoscopy (EGD), a procedure that involves the visual examination of the lining of the esophagus, stomach, and upper duodenum with a flexible fiber-optic endoscope.

Treatment

The objective during treatment of bleeding varices is to stop and/or prevent bleeding and to restore/maintain normal blood circulation throughout the body. Patients with severe bleeding should be treated in intensive care since uncontrolled bleeding can lead to death.

Initial treatment of bleeding varices begins with standard resuscitation, including intravenous fluids and blood transfusions as needed. Definitive treatment is usually endoscopic, with the endoscope used to locate the sites of the bleeding. An instrument, inserted along with the endoscope, is used either to inject these sites with a clotting agent or to tie off the bleeding sites with tiny rubber bands.

Repeated endoscopic treatments (usually four to six) are generally required to eliminate the varices and to prevent the recurrence of bleeding. These endoscopic techniques are successful in about 90% of cases.

Patients who cannot be treated endoscopically may be considered for an alternative procedure called TIPS (transjugular intrahepatic portosystemic shunt). This procedure involves placing a hollow metal tube (shunt) in the liver connecting the portal veins with the hepatic veins (veins that leave the liver and drain to the heart). This shunt lowers the pressure in the portal veins and prevents bleeding and portal hypertension. The TIPS procedure is performed by a radiologist and has become an accepted method for reducing portal vein pressure since 1992. Although the procedure continues to evolve, TIPS can routinely be created in more than 93% of patients.

Medications aimed at controlling bleeding may also be prescribed. These include propanolol, vasopressin, octreotide acetate, and isosorbide mononitrate.

Alternatives

Some alternative treatments are aimed at preventing the cirrhosis of the liver that often causes bleeding varices, and most are effective. However, once a patient has reached the bleeding varice stage, standard intervention to stop the bleeding is required or the patient may die.

Prognosis

Bleeding varices represent one of the most feared complications of portal hypertension. They contribute

to the estimated 32,000 deaths per year attributed to cirrhosis. Half or more of patients who survive episodes of bleeding varices are at risk of renewed esophageal bleeding during the first one to two years. The risk of recurrence can be lowered by endoscopic and drug treatment. Prognosis is usually more related to the underlying liver disease. Approximately 30–50% of people with bleeding varices will die from this condition within the six weeks of the first bleeding episode.

Prevention

The best way to possibly prevent the development or recurrence of bleeding varices is to eliminate the risk factors for cirrhosis of the liver. The most common cause of cirrhosis is prolonged alcohol abuse, and alcohol consumption must be completely eliminated. People with hepatitis B or hepatitis C also have an increased risk of developing cirrhosis of the liver. Vaccination against hepatitis B and avoidance of intravenous drug usage reduce the risk of contracting hepatitis.

Blepharitis *see* **Eyelid disorders**

Blepharoplasty

Definition

Blepharoplasty is a cosmetic surgical procedure that removes fat deposits, excess tissue, or muscle from the eyelids to improve the appearance of the eyes.

Purpose

The primary use of blepharoplasty is for improving the cosmetic appearance of the eyes. In some older patients, however, sagging and excess skin surrounding the eyes can be so extensive that it limits the range of vision. In those cases, blepharoplasty serves a more functional purpose.

Precautions

Before performing blepharoplasty, the surgeon will assess whether the patient is a good candidate for the treatment. A good medical history is important. The surgeon will want to know about any history of thyroid disease, **hypertension**, or eye problems, which may increase the risk of complications.

Description

Blepharoplasty can be performed on the upper or lower eyelid; it can involve the removal of excess skin and fat deposits and the tightening of selected muscles surrounding the eyelids. The goal is to provide a more youthful appearance.

The surgeon will begin by deciding whether excess skin, fat deposits, or muscle looseness are at fault. While the patient is sitting upright, the surgeon will mark on the skin where incisions will be made. Care will be taken to hide the incision lines in the natural skin folds above and below the eye. The patient then receives injections of a local anesthetic to numb the **pain**. Many surgeons also give the patient a sedative intravenously during the procedure.

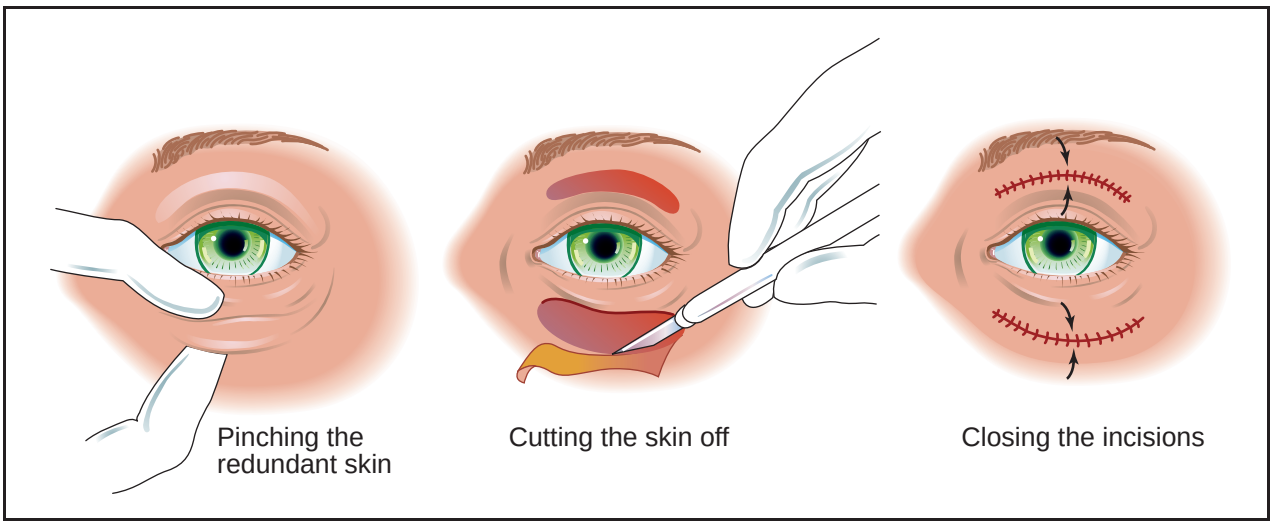
After a small, crescent-shaped section of eyelid skin is removed, the surgeon will work to tease out small pockets of fat that have collected in the lids. If muscle looseness is also a problem, the surgeon may trim tissue or add a stitch to pull it tighter. Then the incision is closed with stitches.

In some patients, fat deposits in the lower eyelid may be the only or primary problem. Such patients may be good candidates for transconjunctival blepharoplasty. In this procedure the surgeon makes no incision on the surface of the eyelid, but instead enters from behind to tease out the fat deposits from a small incision. The advantage of this procedure is that there is no visible scar.

Preparation

Prior to surgery, patients meet with their surgeon to discuss the procedure, clarify the results that can be achieved, and discuss the potential problems that might occur. Having realistic expectations is important in any

WWW.BOOKBAZ.IR



Blepharoplasty is one of the most common cosmetic surgical procedures. The illustration above depicts a procedure to eliminate dermochalasia, or baggy skin, around the eyes. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

cosmetic procedure. Patients will learn, for example, that although blepharoplasty can improve the appearance of the eyelid, other procedures, such as a chemical peel, will be necessary to reduce the appearance of wrinkles around the eye. Some surgeons prescribe vitamin C and **vitamin K** for 10 days prior to surgery in the belief that this helps the healing process. Patients are also told to stop **smoking** in the weeks before and after the procedure, and to refrain from alcohol and **aspirin**.

Aftercare

An antibiotic ointment is applied to the line of stitches for several days after surgery. Patients also take an antibiotic several times a day to prevent infection. Ice-cold compresses are applied to the eyes continuously for the first day following surgery, and several times a day for the next week or so, to reduce swelling. Some swelling and discoloration around the eyes is expected with the procedure. Patients should avoid aspirin or alcoholic beverages for one week and should limit their activities, including bending, straining, and lifting. The stitches are removed a few days after surgery. Patients can generally return to their usual activities within a week to 10 days.

Risks

As with any surgical procedure, blepharoplasty can lead to infection and scarring. Good care of the wound following surgery can minimize these risks. In cases where too much skin is removed from the eyelids, the patient may have difficulty closing his eyes. Dry eye syndrome may develop, requiring the use of artificial tears to lubricate the eye. In a rare complication, called retrobulbar hematoma, a pocket of blood forms behind the eyeball.

Results

Most patients can expect good results from blepharoplasty, with the removal of excess eyelid skin and fat producing a more youthful appearance. Some swelling and discoloration is expected immediately following the procedure, but this clears in time. Small **scars** will be left where the surgeon has made incisions, but these generally lighten in appearance over several months, and, if placed correctly, will not be readily noticeable.

Abnormal results

If too much excess skin is removed from the upper eyelid, the patient may be unable to close his eyes completely; another surgery to correct the defect may be required. Similarly, too much skin can be removed from the lower eyelid, allowing too much of the white of the eye (the sclera) to show. In extreme cases, the lower lid may be pulled down too far, revealing the underlying tissue. Called an ectropion, this too may require a second, corrective surgery. The eye's ability to make tears may also be compromised, leading to dry eye syndrome. Dry eye syndrome is potentially dangerous; in rare cases it leads to damage to the cornea of the eye and vision loss.

Richard H. Camer

Blindness *see* **Visual impairment**

Blood clots

Definition

Blood clots are thickened masses in the blood formed by cell derivatives called platelets in combination with clotting factors. Clots halt the bleeding from a cut or injury; however, clots that form within blood vessels and fail to dissolve can cause serious medical complications. **Deep vein thrombosis** (DVT) is a clot that forms in a vein of the lower leg, thigh, or pelvis. Portions of such clots, known as emboli, can break off and travel through the bloodstream to the lungs, causing **pulmonary embolism** (PE). Venous thrombi are clots that form in the veins of the arms or other parts of the body. A clot in a coronary artery can cause a **heart attack**. A blood clot in an artery in the brain can cause an ischemic **stroke**.

Demographics

Blood clots are common and often harmless. However, DVT affects as many as 600,000 Americans every year, leading to more than 250,000 hospitalizations. As many as 100,000 Americans die annually from PE. Blood clots also affect one or two out of every 1,000 pregnancies. Men and women are at similar risk for blood clots. People over age 60 are at higher risk.

Description

When a blood vessel wall is damaged from a cut or wound, a series of reactions occur to coagulate the blood and form a clot that halts bleeding. Platelets—disk-like blood cell derivatives—clump together in association with various proteins, including collagen, thrombin, fibrin, and von Willebrand factor. The series of reactions leading to clot formation is balanced by other reactions that stop the clotting process and dissolve the clot after the blood vessel has healed. However, sometimes blood clots form too easily in a process called hypercoagulation or do not dissolve properly. Although blood clots are not necessarily dangerous, they sometimes form in blood vessels and can break off, travel through the circulatory system, and become lodged in other parts of the body where they limit or block the flow of blood. Thrombi are clots such as DVT that remain where they form. DVT most often occurs in the lower leg, where it can cause swelling known as **thrombophlebitis**. Clots that break off and travel through the circulatory system are known as emboli.

Depending on where a clot forms or lodges, it can cause severe damage or death.

- DVT in an arm or leg causes swelling, pain, redness, and warmth and can break off and cause PE.
- A blood clot that blocks an artery in or leading to the brain can cause an ischemic stroke, in which brain tissue served by that artery is deprived of oxygenated blood and begins to die. Cerebral thrombosis, in which a clot forms in an artery in the brain, often as a result of atherosclerosis (hardening of the arteries), is the most common type of stroke. Cerebral embolism is an ischemic stroke caused by a blood clot that moves through the circulatory system to a carotid artery in the neck or an artery in the brain.
- Transient ischemic attacks (TIAs), or mini-strokes, are caused by the blockage of a very small artery or the intermittent or temporary obstruction of a larger artery.
- A blood clot that blocks a coronary artery can cause a heart attack.
- A blood clot in the kidneys can cause kidney failure.
- Blood clots during pregnancy can result in miscarriage, stillbirth, or high blood pressure and other late-pregnancy symptoms (preeclampsia).

Risk factors

Risk factors for blood clots include the following:

- smoking
- overweight or obesity
- estrogen-containing medications, including birth control pills and hormone replacement therapy
- a previous clot or a family history of blood clots
- genetic factors and inherited disorders that affect clotting proteins or factors for dissolving clots
- atherosclerosis, in which plaque that builds up inside arteries can rupture and cause clot formation

WWW.BOOKBAZ.IR

- diabetes, which increases the risk of plaque buildup
- high blood pressure
- dehydration, which causes narrowing of blood vessels and thickening of the blood
- abdominal cancer and cancers that increase clotting proteins
- vasculitis or inflamed blood vessels
- heart failure, in which slowly flowing blood is prone to clotting
- atrial fibrillation, which causes blood to pool in the upper chambers of the heart (atria) and can lead to clot formation, the most common cause of cerebral embolism
- peripheral artery disease (PAD), atherosclerosis in the pelvis and legs
- high levels of homocysteine, which is associated with vascular disease
- HIV/AIDS and some HIV treatments

Limited mobility and prolonged bed rest are risk factors for blood clots. Sitting for longer than 6–8 hours, as during travel, or immobility from illness, surgery, or **paralysis** can lead to blood clots. Surgery stimulates the clotting response, and some types of surgery or injury, especially blood vessel surgeries and hip replacements, present particular risk. Organ transplants and implanted devices, including artificial hips, catheters, and shunts, increase the risk of blood clots.

Pregnancy and **childbirth** increase platelets and clotting factors, and the enlarged uterus can compress veins, increasing the risk of clots. Pregnant women older than 35 who are overweight or who smoke are at higher risk of blood clots during pregnancy, as are pregnant women with pre-existing diabetes, **varicose veins**, or inflammatory bowel disease. Women are also at risk for blood clots during the first six weeks after giving birth. Obese new mothers have a four-fold increased risk of blood clots. Cesarean delivery, premature delivery, bleeding during pregnancy, or giving birth at least three times doubles the risk of blood clots. **Stillbirth** increases the risk six-fold.

Causes and symptoms

As is apparent from the large number of risk factors, there are many causes of blood clots, including genetic factors, acquired factors triggered by a disease or condition, and environmental and lifestyle factors. DVT is commonly caused by prolonged inactivity or immobility that decreases blood flow in the lower legs.

Blood clots often do not cause symptoms until they become large enough to block the flow of blood through an artery or vein, when symptoms may develop suddenly in the area of the clot. Symptoms depend on the location of the blood clot. Symptoms of DVT or PAD include **pain** or tenderness, warmth or redness of the skin, and sudden swelling in the affected limb. Symptoms of PE, a heart attack, or stroke are medical emergencies. A high **fever**, **shortness of breath**, rapid pulse, chest pain, or pain in the arms, back, neck, or jaw may indicate a PE or heart attack from a blood clot. Stroke symptoms depend on the part of the brain that is deprived of oxygen and how large an area is affected. Stroke symptoms can include the following:

- paralysis and/or loss of sensation, especially on one side of the body
- slurred speech or communication difficulties
- severe headache
- mental confusion
- dizziness
- vision problems
- loss of consciousness

Diagnosis

Examination

A physical exam is performed. The medical history will include risk factors for blood clots, genetic disorders, and medications. A neurologic exam is performed if there are indications of a stroke.

Tests

Blood tests include red and white blood cell and platelet counts.

Procedures

Various imaging procedures are used to diagnose blood clots.

- Doppler or duplex ultrasound transforms sound waves reflected from tissues into moving images on a screen that may reveal a clot, as well as blood flow near the clot and any other abnormalities.
- Computed tomography (CT) scans may be used to image blood vessels. A special dye called a contrast agent may be injected before the exam to help highlight the blood vessels.
- Magnetic resonance angiography uses magnetic resonance imaging (MRI) to image the blood vessels and may also involve injection of a contrast dye.

KEY TERMS

Anticoagulant—Blood thinner; a medication that prevents coagulation or clotting of the blood.

Atherosclerosis—Thickening and hardening of the inner walls of arteries due to the accumulation of plaque, which can lead to blood clots.

Cerebral embolism—Ischemic stroke caused by a blood clot that travels to the brain from elsewhere in the body.

Cerebral thrombosis—Ischemic stroke caused by a blood clot that forms in an artery in the brain.

Deep vein thrombosis (DVT)—A clot in a deep vein, as in the leg or pelvis.

Embolus (pl. emboli)—A clot that forms in one part of the body and breaks off, travels through the bloodstream, and lodges elsewhere in the circulatory system.

Fibrin—The fibrous protein of blood clots.

Homocysteine—An amino acid that, when present at high levels in the blood, may be associated with the formation of blood clots.

Hypercoagulation—Excessive clotting of the blood.

Ischemic stroke—Insufficient blood supply to a part of the brain due to a blood clot.

Peripheral arterial disease (PAD)—Damage to the arteries outside of the heart; especially narrowing or obstruction of an artery supplying a leg.

Platelets—Blood components that assist clotting.

Pulmonary embolism (PE)—A blood clot that travels to a pulmonary artery of the lung, usually from a vein in the leg or pelvis.

Thrombus (pl. thrombi)—A blood clot that forms inside an intact blood vessel and remains there.

Tissue plasminogen activator (tPA)—A drug that can dissolve a blood clot in the brain and halt an ongoing ischemic stroke.

- Venography is less commonly performed. It uses x rays to image veins following injection of a contrast material.

Treatment

Traditional

Although blood clots are most often treated with drugs, surgery is sometimes required to remove a clot blocking a pelvic or abdominal vein or a chronic and disabling clot. A cardiovascular surgeon or interventional radiologist may perform balloon **angioplasty** or insert a stent to open a narrowed or damaged vessel. Rarely, a filter is installed to block a clot from lodging in the lungs. Blood clots causing acute ischemic strokes are sometimes removed mechanically with a wire threaded to the brain through an artery in the groin. Such devices can also deliver clot-busting drugs to the site. A corklike device called a Merci Retriever has been used since 2004. A next-generation clot-extraction device that uses aspiration alone to remove a clot causing an acute ischemic stroke was approved for use in 2013.

Drugs

Thrombolytics, or so-called clot-busters, are injected for emergency treatment of life-threatening blood clots. Tissue plasminogen activator (tPA), a genetically engineered form of the body's natural clot-buster, is effective for ongoing ischemic strokes if administered within three hours of the onset of symptoms.

Anticoagulants or blood thinners are used to prevent existing clots from enlarging and new clots from forming, although they will not break up existing clots. Heparin and warfarin (Coumadin) are the most common anticoagulants. Injected heparin acts immediately to inhibit platelet clumping and may be prescribed after surgery, when clotting is most likely. Heparin or rivaroxaban (Xarelto) are usually prescribed after **hip replacement** surgery to prevent DVT and PE. Warfarin is taken orally and requires several days to become effective. Warfarin levels in the blood must be routinely monitored and the dosage adjusted, because levels can be affected by diet: too little warfarin can lead to clotting and too much can cause life-threatening bleeding. In 2012, the U.S. Food and Drug Administration (FDA) approved the anticoagulant apixaban (Eliquis), which its manufacturer anticipated would replace warfarin, especially in patients with **atrial fibrillation** who must take anticoagulants for the rest of their lives.

Natural human anticoagulants are used for short-term treatment. Protein C may be given to prevent clot formation associated with **septic shock** or for patients with a protein C deficiency, since protein C is necessary to prevent a serious side effect of warfarin that can damage and destroy skin cells. Antithrombin factor is administered to patients with an antithrombin deficiency that prevents clots from dissolving.

WWW.BOOKBAZ.IR

Alternatives

Various alternative remedies have been suggested as blood thinners, including garlic, onions, and cayenne pepper. An Australian study found that a daily glass of tomato juice reduces the risk of DVT, stroke, and cardiovascular disease. It has been suggested that Pinokinase, a combination of pine bark and soy extracts, can be effective in controlling DVT in airplane passengers.

Home remedies

Despite the large, competitive market in blood thinners, several studies have indicated that daily low-dose (100 mg) **aspirin** is as effective as long-term use of warfarin in preventing blood clots and at a fraction of the price.

Prognosis

Excessive blood clotting can usually be controlled with medications. However PE, stroke, and heart attacks are potentially fatal. As many as one in three PEs are fatal, usually within 30–60 minutes. Many people with diabetes eventually die of blood clot-related complications.

Prevention

A study of more than 30,000 people, aged 45 and older, found that the risk of blood clots could be reduced by following the American Heart Association's "Life's Simple 7":

- adequate physical activity
- not smoking
- following a healthy diet
- maintaining a healthy weight
- controlling blood sugar
- controlling blood pressure
- controlling cholesterol levels

Other preventive measures include the following:

- avoiding estrogen-containing medications
- taking blood-thinning medications as prescribed
- wearing support stockings to reduce the risk of DVT
- treating conditions such as PAD, heart disease, and diabetes

A World Health Organization study found that the risk of travel-related blood clots is relatively low, with about one clot per 6,000 trips of four hours or more. Drinking plenty of fluids, avoiding clothing that is tight around the waist, stretching the calves and flexing the ankles, and moving about hourly during long trips can help prevent clots. Since the body's clotting mechanism is particularly active following surgery, patients are routinely advised to avoid travel for about a month after surgery.

Blood crossmatching *see* **Blood typing and crossmatching**

Blood culture

Definition

A blood culture is done when a person has symptoms of a blood infection, also called **bacteremia**. Blood is drawn from the person one or more times and is tested in a laboratory to find and identify any microorganism present and growing in the blood. If a microorganism is found, more testing is done to determine the **antibiotics** that will be effective in treating the infection.

Purpose

Bacteremia is a serious clinical condition and can lead to death. To give the best chance for effective treatment and survival, a blood culture is done as soon as an infection is suspected.

Symptoms of bacteremia are **fever**, chills, mental confusion, **anxiety**, rapid heart beat, hyperventilation, blood clotting problems, and **shock**. These symptoms are especially significant in a person who already has another illness or infection, is hospitalized, or has trouble fighting infections because of a weak immune system. Often, the blood infection results from an infection somewhere else in the body that has spread.

Additionally, blood cultures are done to find the causes of other infections. These include bacterial **pneumonia** (an infection of the lung), and infectious **endocarditis** (an infection of the inner layer of the heart). Both of these infections leak bacteria into the blood.

After a blood infection has been diagnosed, confirmed by culture, and treated, an additional blood culture may be done to make sure the infection is gone.

Description

Culture strategies

There are many variables involved in performing a blood culture. Before the person's blood is drawn, the physician must make several decisions based on a knowledge of infections and the person's clinical condition and medical history.

Several groups of microorganisms, including bacteria, viruses, mold, and yeast, can cause blood infections. The bacteria group can be further broken down into aerobes and anaerobes. Most microbes do not need oxygen to live. They can grow with oxygen (aerobic microbes) or without oxygen (anaerobic microbes).

Based on the clinical condition of the patient, the physician determines what group of microorganisms is likely to be causing the infection and then orders one or more specific types of blood culture, including aerobic, anaerobic, viral, or fungal (for yeasts and molds). Each specific type of culture is handled differently by the laboratory. Most blood cultures test for both aerobic and anaerobic microbes. Fungal, viral, and mycobacterial blood cultures can also be done, but are less common.

The physician must also decide how many blood cultures should be done. One culture is rarely enough; two to three are usually adequate. Four cultures are occasionally required. Some factors influencing this decision are the specific microorganisms the physician expects to find based on the person's symptoms or previous culture results, and whether or not the person has had recent antibiotic therapy.

The time at which the cultures are to be drawn is another decision made by the physician. During most blood infections (called intermittent bacteremia) microorganisms enter the blood at various time intervals. Blood drawn randomly may miss the microorganisms. Since microorganisms enter the blood 30–90 minutes before the person's fever spikes, collecting the culture just after the fever spike offers the best likelihood of finding the microorganism. The second and third cultures may be collected at the same time, but from different places on the person, or spaced at 30-minute or one-hour intervals, as the physician chooses. During continuous bacteremia, such as

WWW.BOOKBAZ.IR

infective endocarditis, microorganisms are always in the blood and the timing of culture collection is less important. Blood cultures should always be collected before antibiotic treatment has begun.

Laboratory analysis

Bacteria are the most common microorganisms found in blood infections. Laboratory analysis of a bacterial blood culture differs slightly from that of a fungal culture and significantly from that of a viral culture.

Blood is drawn from a person and put directly into a blood culture bottle containing a nutritional broth. After the laboratory receives the blood culture bottle, several processes must be completed:

- provide an environment for the bacteria to grow
- detect the growth when it occurs
- identify the bacteria that grow
- test the bacteria against certain antibiotics to determine which antibiotic will be effective

There are several types of systems, both manual and automated, available to laboratories to carry out these processes.

The broth in the blood culture bottle is the first step in creating an environment in which bacteria will grow. It contains all the nutrients that bacteria need to grow. If the physician expects anaerobic bacteria to grow, oxygen will be kept out of the blood culture bottle; if aerobes are expected, oxygen will be allowed in the bottle.

The bottles are placed in an incubator and kept at body temperature. They are watched daily for signs of growth, including cloudiness or a color change in the broth, gas bubbles, or clumps of bacteria. When there is evidence of growth, the laboratory does a gram stain and a subculture. To do the gram stain, a drop of blood is removed from the bottle and placed on a microscope slide. The blood is allowed to dry and then is stained with purple and red stains and examined under the microscope. If bacteria are seen, the color of stain they picked up (purple or red), their shape (such as round or rectangular), and their size provide valuable clues as to what type of microorganism they are and what antibiotics might work best. To do the subculture, a drop of blood is placed on a culture plate, spread over the surface, and placed in an incubator.

If there is no immediate visible evidence of growth in the bottles, the laboratory looks for bacteria by doing gram stains and subcultures. These steps are repeated daily for the first several days and periodically after that.

When bacteria grows, the laboratory identifies it using biochemical tests and the gram stain. Sensitivity testing, also called antibiotic susceptibility testing, is also done. The bacteria are tested against many different antibiotics to see which antibiotics can effectively kill it.

All information is passed on to the physician as soon as it is known. An early report, known as a preliminary report, is usually available after one day. This report will tell if any bacteria have been found yet and, if so, the results of the gram stain. The next preliminary report may include a description of the bacteria growing on the subculture. The laboratory notifies the physician immediately when an organism is found and as soon as sensitivity tests are complete. Sensitivity tests may be complete before the bacteria is completely identified. The final report may not be available for five to seven days. If bacteria was found, the report will include its complete identification and a list of the antibiotics to which the bacteria is sensitive.

One automated system is considered one of the most important technical advances in blood cultures. It is called continuous-monitoring blood culture systems (CMBCS). The instruments automatically monitor the bottles containing the patient blood for evidence of microorganisms, usually every 10 minutes. Many data points are collected daily for each bottle, and fed into a computer for analysis. Sophisticated mathematical calculations can determine when microorganisms have grown. This, combined with more frequent blood tests, make it possible to detect microbial growth earlier. In addition, all CMBCS instruments have the detection system, incubator, and agitation device in one unit.

Preparation

Ten milliliters (mL) of blood is usually needed for each blood culture bottle. First a healthcare worker locates a vein in the inner elbow region. The area of skin where the blood will be drawn must be disinfected to prevent any microorganisms on a person's skin from entering the blood culture bottle and contaminating it. The area is disinfected by wiping the area with alcohol in a circular fashion, starting with tiny circles at the spot where the needle will puncture the skin and enlarging the size of the circles while wiping away from the puncture site. The same pattern of wiping is repeated using an iodine or iodophor solution. The top of the bottle is disinfected using alcohol. After the person's skin has been disinfected, the healthcare worker draws the blood and about 10 mL of blood is injected into each blood culture bottle.

The type of bottles used will vary based on whether the physician is looking for bacteria (aerobes or anaerobes), yeast, mold, or viruses.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs relieve discomfort.

Risks

The most common risks of a blood culture are minor bleeding and bruising.

Results

Normal results will be negative. A single negative culture does not rule out a blood infection, however; false negatives can occur if the person was started on antibiotics before the blood was drawn, if the environment for growth was not right, if the timing was off, or for some unknown reason. Three negative cultures may be enough to rule out bacteremia in the case of endocarditis.

Abnormal results

The physician's skill in interpreting the culture results and assessing the person's clinical condition is essential in distinguishing a blood culture that is truly positive from a culture that is positive because it became contaminated. In true bacteremia, the patient's clinical condition should be consistent with a blood infection caused by the microorganism that was found. The microorganism is usually found in more than one culture, it usually grows soon after the bottles are incubated, and it is often the cause of an infection somewhere else in the person's body.

When the culture is positive because of contamination, the patient's clinical condition usually is not consistent with an infection from the identified microorganism. In addition, the microorganism is often one commonly found on skin, rarely causes infection, is found in only one bottle, and may appear after several days of incubation. More than one microorganism often grow in contaminated cultures.

REVISED BY L. FLEMING FALLON, JR., MD, DrPH

Blood donation and registry

Definition

Blood donation, also called blood banking, refers to the process of collecting, testing, preparing, and storing whole blood and blood components intended primarily for **transfusion**. Blood donors are typically unpaid volunteers, but they may also be paid by commercial blood donation and processing enterprises, such as independent blood banks and donor centers. Blood registry refers to the collection and sharing of data about donated blood and donors. Donors who have been determined to be temporarily

WWW.BOOKBAZ.IR

or permanently ineligible to donate blood are listed in a confidential national database known as the Donor Deferral Register. The quality and safety of the U.S. blood supply is governed by physician-established guidelines for the practice of blood banking as found in the Standards of the American Association of Blood Banks (AABB) and through the organization's inspection and accreditation program. The U.S. Food and Drug Administration (FDA) controls federal licensure of blood banks. Hospital blood banks are also inspected by the College of American Pathologists (CAP) and the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations).

Purpose

Blood is collected, processed, stored, and distributed to maintain an adequate supply of whole blood and blood components for transfusion as needed. Blood replacement may be needed by people who have lost blood through accidents, **burns**, hemorrhage, or surgery. Blood or blood components are also used in the treatment of certain types of anemia, various disease conditions, and for medical research.

Healthy donors may be called upon to donate periodically to help maintain the overall blood supply or when their specific blood type is needed. People may sometimes donate blood to benefit a specific person. Directed donor blood is reserved for an intended recipient, such as a family member or friend; it is tested and processed as all other donated blood to ensure that it is appropriate for the recipient. People preparing for elective surgery may have their blood collected and held, and then returned to them if needed during their surgery. This process is known as autologous blood donation. Donors are advised to give blood only once in an eight-week period to maintain the iron stores in their blood. Autologous donors may donate more often if it is determined by their physician to be to their benefit.

Blood is donated as whole blood. It is collected in a plastic bag containing an anticoagulant that will keep the blood from clotting and allow it to be separated into multiple components. By dividing blood into components that each offer different clinical benefits, one unit of donated blood can meet the transfusion needs for more than one person. This practice is essential to meet the constant demand for blood; according to the American Red Cross, someone in the United States needs blood approximately every two seconds, and 30 million blood components are transfused every year.

Whole blood and blood components are used in various ways to meet the clinical needs of recipients. Whole blood is sometimes used to replace blood volume when a significant amount of blood has been lost through an accident or surgery. Red blood cells, which carry oxygen, are used to treat certain **anemias** and are often the preferred component when multiple transfusions are being administered to one person, as in open heart surgery or organ transplants. Platelets, part of the complex coagulation (clotting) system that helps control bleeding, are commonly used in the treatment of acute leukemia and some types of cancer. Fresh frozen plasma, which contains critical coagulation factors, is used to control bleeding in people who lack these factors. Cryoprecipitated (prepared from frozen plasma) antihemophilic factor (AHF) is transfused to provide a specific coagulation factor that is deficient in **hemophilia** and other diseases. Blood for transfusion is requested by physicians. Pre-transfusion testing and issuance of blood and components to the recipients is performed by a transfusion service, which is commonly provided or supervised by a hospital blood bank.

Demographics

The *National Blood Collection and Utilization Survey* reported that more than 17 million units of whole blood (one unit of whole blood equals 450 mL, or about one pint) were donated in the United States in 2008, of which about 253,000 were autologous donations. The supply was donated by more than 10 million people, although it is estimated that fewer than 5% of those eligible donate. More than 40% of donated blood is processed by the American Red Cross; the rest is distributed by hospital blood banks, community blood centers, mobile blood drives, and independent blood banks.

Description

The actual process of donating whole blood takes about 20 minutes. The donor will either lie down or will sit in a special donor chair that elevates the lower body and legs. After selecting an appropriate vein, the phlebotomist (an individual trained in blood collection technique) will clean the arm well at the site of the needle puncture (venipuncture). With a tourniquet tightly in place on the donor's arm, a sterile needle is inserted into a vein. As the tourniquet is released, blood flows through plastic tubing into a plastic blood bag. The donor may be asked to open and close a fist to encourage blood to flow. Usually only one unit of blood is collected. Pressure is applied to the site of the venipuncture until the blood flow has been

stopped. Donors are then escorted to an observation area, given light refreshments that include liquid, and allowed to rest. Positive identification of the donor and the blood bag from that donor are essential. The same unique identification number is assigned to the bag, all samples from the bag used for testing, and on all donor and testing records.

Plasma, the liquid portion of whole, anticoagulated blood in which blood cells, coagulation factors, and other blood constituents are suspended, is also collected. This is often done by commercial enterprises that sell it to companies manufacturing clotting factors and specific plasma protein products, or to companies and institutions engaged in medical research. Plasma is collected using a process known as apheresis, in which whole blood is collected, the desired blood component is removed, and the remainder is returned to the donor. Collecting plasma generally takes one to two hours. Apheresis may also be used to collect other blood components, such as platelets and granulocytes.

Different blood components vary in how long they can be stored. Red blood cells can be refrigerated for up to 42 days or coated with a protective agent and frozen at extremely low temperatures in liquid nitrogen, a process that preserves them for up to ten years. Platelets must be used soon after they are prepared; they are stored at room temperature for no more than five days. Fresh frozen plasma and cryoprecipitated AHF can be kept for as long as one year.

To ensure the safety of the blood supply, a multitiered process of donor screening and deferral is employed. This process involves donor education; taking a detailed **health history** of each prospective donor; giving potential donors a simple **physical examination**, which includes measuring blood pressure and pulse rate; taking a few drops of blood to test for hemoglobin, the iron-bearing protein in blood; and measuring blood cell volume. These tests will indicate general health and help ensure that donation will not contribute to anemia in the donor. At any point in the process, a potential donor may be "deferred," or determined to be ineligible to donate blood. This deferral may be temporary or permanent, depending on the reason. Potential donors are also encouraged to "self-defer," or voluntarily decline to donate, rather than put future blood recipients at risk.

In general, blood donors must be at least 17 years old (some states allow younger people to donate blood with their parents' consent), must weigh at least 110 lb. (50 kg), and must be in good health. Donors with a history of heart, lung, or **liver disease** or who are pregnant are usually deferred. Donors can be disqualified if they are known to have engaged in behavior that put them at risk of infection (such as having a recent tattoo, having had sex with people in high-risk groups, having used illegal intravenous drugs, having had certain diseases, or having been raped) or have spent time in specific parts of the world, such as areas where **malaria** may be prevalent.

Preparation

All donated blood is extensively tested before being distributed for use by transfusion services. The first step is determining the blood type, which is the primary indication of who can receive the blood. Blood is also screened for any irregular antibodies that could cause complications for the recipients. In addition, donor blood is screened for infectious diseases, such as hepatitis, **AIDS**, and **syphilis**, by testing for specific markers of these diseases that will appear in the blood of those infected. These include: **Hepatitis B** surface antigen (donors with this antigen are immune and can be accepted), hepatitis B core antigen, **hepatitis C** virus antibody, HIV-1 and HIV-2 antibodies, HIV p24 antigen, and HTLV-I and HTLV-II antibodies. Other tests may be performed if a recipient's doctor requests them.

In order to detect the greatest possible number of infections, when present at even the lowest levels in donor blood, these screening tests are extremely sensitive. For this reason, however, donors sometimes receive false positive test results. In these cases, more specific confirmatory tests are performed to help rule out false positive results. Blood found to be unsuitable for transfusion is discarded, and all items coming into direct contact with donors are used only once and then discarded. Donors of infected blood are entered into the Donor Deferral Register to prevent subsequent donation of their blood at other blood donation facilities.

There are eight major blood types comprising four ABO groups (A, B, AB, and O), and the presence or absence of the Rh factor, designated as either type Rh positive (+) or type Rh negative (-). These types and their approximate distribution in the U.S. population are as follows: O+ (38%), O- (7%), A+ (34%), A- (6%), B+ (9%), B- (2%), AB+ (3%), AB- (1%). In an emergency, when there may be no time for compatibility testing, anyone can safely receive type O red blood cells, and people with this blood type are known as "universal donors." People with type AB blood, known as "universal recipients," can receive

WWW.BOOKBAZ.IR

any type of red blood cells and can give plasma to all blood types. Receiving the wrong blood type can result in the destruction of red cells in the recipient's body and even death. For this reason, the transfusion service must conduct more pre-transfusion testing to determine the compatibility of the donor blood with the blood of the recipient. This compatibility testing, known as type and cross match, begins with matching the major blood types. Additional testing will include antibody screening of the recipient and, if specific antibodies are found, testing of other blood groups (the MN group or Kell and Lewis groups, for example) will be done to find compatible donor blood.

Risks

Thanks to the use of a multitiered donor screening system and advances in the effectiveness of screening tests, the risk of transmitting infectious diseases to recipients via transfusion has been significantly diminished. Nonetheless, there is still a minuscule risk that blood recipients could contract human **immunodeficiency** virus (HIV), hepatitis, or other diseases via transfusion. Other diseases that are of particular concern to blood-collection agencies include: **babesiosis**, Chagas disease, human T-lymphotropic virus (HTLV-I and II), cytomegalovirus (CMV), **Lyme disease**, malaria, Creutzfeldt-Jakob disease, and a new variant of Creutzfeldt-Jakob disease.

There are few risks to healthy donors when AABB standards for donation are followed. People who donate blood replace the fluid they lose within 24 hours and the red cells within two months. A person can safely donate blood once every eight weeks. Donors' blood will be tested prior to donation to determine their eligibility; those ineligible will be advised of the temporary or permanent reasons for being disqualified. Their names will be placed on the national deferral registry to prevent donation at other sites and to help protect the blood supply.

Medical professionals who draw the blood of eligible donors will advise donors of any necessary precautions following donation. Most blood donors suffer no significant aftereffects. Occasionally, donors may feel faint or dizzy, nauseous, or have tenderness, redness, or a bruise where the needle was inserted to draw their blood. More serious complications, which rarely occur, may include **fainting**, **muscle spasms**, or nerve damage.

AABB standards are designed to protect donors and recipients and especially to help ensure that compatible blood is transfused to each recipient. The accurate labeling of blood, blood components, and donor records and the recording of all data is essential from the time blood is collected, through testing and preparation, and through pre-transfusion testing and issuance of the blood or blood component. Autologous blood donors run a very small risk of having the wrong blood returned to them due to clerical error. There is also a faint possibility of bacterial contamination of the autologous blood. These rare occurrences apply to all other transfusions as well.

KEY TERMS

Apheresis—Extraction of a specific component from donated blood, with the remainder returned to the donor.

Autologous donation—Blood donated for the donor's own use.

Granulocytes—White blood cells.

Plasma—The liquid part of anticoagulated blood; referred to as serum when part of a clotted blood sample.

Platelets—Tiny, disk-like elements of plasma that promote clotting.

Blood gas analysis

Definition

Blood gas analysis, also called arterial blood gas (ABG) analysis, is a test that measures the amounts of oxygen and carbon dioxide in the blood, as well as the acidity (pH) of the blood.

Purpose

An ABG analysis evaluates how effectively the lungs are delivering oxygen to the blood and how efficiently they are eliminating carbon dioxide from it. The test also indicates how well the lungs and kidneys are interacting to maintain normal blood pH (acid-base balance). Blood gas studies are usually done to assess respiratory disease and other conditions that may affect the lungs, and to manage patients receiving **oxygen therapy** (**respiratory therapy**). In addition, the acid-base component of the test provides information on kidney function.

Description

Blood gas analysis is performed on blood from an artery. It measures the partial pressures of oxygen and carbon dioxide in the blood, as well as oxygen content, oxygen saturation, bicarbonate content, and blood pH.

Oxygen in the lungs is carried to the tissues through the bloodstream, but only a small amount of this oxygen can actually dissolve in arterial blood. How much dissolves depends on the partial pressure of the oxygen (the pressure that the gas exerts on the walls of the arteries). Therefore, testing the partial pressure of oxygen is actually measuring how much oxygen the lungs are delivering to the blood. Carbon dioxide is released into the blood as a by-product of cell metabolism. The partial carbon dioxide pressure indicates how well the lungs are eliminating this carbon dioxide.

The remainder of oxygen that is not dissolved in the blood combines with hemoglobin, a protein-iron compound found in the red blood cells. The oxygen content measurement in an ABG analysis indicates how much oxygen is combined with the hemoglobin. A related value is the oxygen saturation, which compares the amount of oxygen actually combined with hemoglobin to the total amount of oxygen that the hemoglobin is capable of combining with.

Carbon dioxide dissolves more readily in the blood than oxygen does, primarily forming bicarbonate

WWW.BOOKBAZ.IR

A blood gas analyzer from Corning Corporation. *(Hank Morgan/Photo Researchers, Inc.)*

and smaller amounts of carbonic acid. When present in normal amounts, the ratio of carbonic acid to bicarbonate creates an acid-base balance in the blood, helping to keep the pH at a level where the body's cellular functions are most efficient. The lungs and kidneys both participate in maintaining the carbonic acid-bicarbonate balance. The lungs control the carbonic acid level and the kidneys regulate the bicarbonate. If either organ is not functioning properly, an acid-base imbalance can result. Determination of bicarbonate and pH levels, then, aids in diagnosing the cause of abnormal blood gas values.

The procedure

The blood sample is obtained by arterial puncture (usually in the wrist, although it could be in the groin or arm) or from an arterial line already in place. If a puncture is needed, the skin over the artery is cleaned with an antiseptic. A technician then collects the blood with a small sterile needle attached to a disposable syringe. The patient may feel a brief throbbing or cramping at the site of the puncture. After the blood is drawn, the sample must be transported to the laboratory as soon as possible for analysis.

Preparation

There are no special preparations. Patients have no restrictions on drinking or eating before the test. If the patient is receiving oxygen, the oxygen concentration must remain the same for 20 minutes before the test; if the test is to be taken without oxygen, the gas must be turned off for 20 minutes before the test is taken. The patient should breathe normally during the test.

Aftercare

After the blood has been taken, the technician or the patient applies pressure to the puncture site for 10–15 minutes to stop the bleeding, and then places a dressing over the puncture. The patient should rest quietly while applying the pressure to the puncture site. Healthcare workers will observe the patient for signs of bleeding or circulation problems

Risks

Risks are very low when the test is done correctly. Risks include bleeding or bruising at the site, or delayed bleeding from the site. Very rarely, there may be a problem with circulation in the puncture area.

Results

Normal blood gas values are as follows:

- partial pressure of oxygen (PaO_2): 75–100 mm Hg
- partial pressure of carbon dioxide ($PaCO_2$): 35–45 mm Hg
- oxygen content (O_2CT): 15–23%
- oxygen saturation (SaO_2): 94–100%
- bicarbonate (HCO_3): 22–26 mEq/liter
- pH: 7.35–7.45

Abnormal results

Values that differ from those listed may indicate respiratory, metabolic, or **kidney disease**. These results also may be abnormal if the patient has experienced **trauma** that may affect breathing (especially head and neck injuries). Disorders, such as anemia, that affect the oxygen-carrying capacity of blood, can produce an abnormally low oxygen content value.

KEY TERMS

Acid-base balance—The condition that exists when the body's carbonic acid-bicarbonate buffer system is in equilibrium, helping to maintain the blood pH at a normal level of 7.35–7.45.

Hemoglobin—A protein-iron compound in red blood cells that functions primarily in carrying oxygen from the lungs to the tissues of the body.

pH—A measure of the acidity of a solution. Normal blood pH ranges from 7.35–7.45.

Blood sugar tests

Definition

Blood sugar tests include several different tests that measure the amount of sugar (glucose) in a person's blood. These tests are performed either on an empty stomach, or after consuming a meal or premeasured glucose drink. Blood sugar tests are done primarily to diagnose and evaluate a person with **diabetes mellitus**.

Purpose

The body uses sugar, also called glucose, to supply the energy it needs to function. People get sugar from their diet and from their body tissues. Insulin is made by the pancreas and affects the outer membrane of cells, making it easy for glucose to move from the blood into the cells. When insulin is active, blood glucose levels fall. Sugar from body tissues is stored in the form of glycogen. When glycogen is active, blood glucose levels rise.

After a meal, blood glucose levels rise sharply. The pancreas responds by releasing enough insulin to take care of all the newly added sugar found in the body. The insulin moves the sugar out of the blood and into the cells. Only then does the blood sugar start to level off and begin to fall. A person with diabetes mellitus either does not make enough insulin, or makes insulin that does not work properly. The result is blood sugar that remains high, a condition called hyperglycemia.

Diabetes must be diagnosed as early as possible. If left untreated, it can damage or cause failure of the eyes, kidneys, nerves, heart, blood vessels, and other body organs. **Hypoglycemia**, or low blood sugar, also may be discovered through blood sugar testing. Hypoglycemia is caused by various hormone disorders and **liver disease**, as well as by too much insulin.

Description

There are a variety of ways to measure a person's blood sugar.

Whole blood glucose test

Whole blood glucose testing can be performed by a person in his or her home, and kits are available for this purpose. The person pricks his or her finger (a finger stick) with a sterile sharp blade from the kit. A single drop of blood is placed on a strip in a portable instrument called a glucometer. The glucometer quickly determines the blood sugar and shows the results on a small screen in usually a few seconds.

New technologies for monitoring glucose levels will help diabetics better control their glucose levels. These tests are particularly important for children and adolescents. In mid-2002, the U.S. Food and Drug Administration (FDA) approved a new home test for use by children and adolescents (it had already been approved for adults) called the Cygnus GlucoWatch biographer that helped better detect hypoglycemia. Studies show that more frequent checks are better; new monitors such as this allow for simpler frequent testing. Continuous monitoring was in development in early 2004, as a company called TheraSense Inc. received preapproval from the FDA for clinical trials on its home continuous glucose monitor. The monitor was designed to provide users with real-time glucose data, alarms for hypoglycemia and hyperglycemia and to show trends in their blood sugar levels.

WWW.BOOKBAZ.IR

Fasting plasma glucose test

The fasting plasma glucose test is done on an empty stomach. For the eight hours before the test, the person must fast (nothing to eat or drink, except water). The person's blood is drawn from a vein by a healthcare worker. The blood sample is collected into a tube containing an anticoagulant. Anticoagulants stop the blood from clotting. In the laboratory, the tube of blood spins at high speed within a machine called a centrifuge. The blood cells sink to the bottom and the liquid stays on the top. This straw-colored liquid on the top is the plasma. To measure the glucose, a person's plasma is combined with other substances. From the resulting reaction, the amount of glucose in the plasma is determined.

Oral glucose tolerance test

The oral glucose tolerance test is conducted to see how well the body handles a standard amount of glucose. This test measures the amount of glucose in a person's plasma before and two hours after drinking a large premeasured beverage containing glucose. The person must eat a consistent diet, containing at least 5.25 oz. (150g) of carbohydrates each day, for three days before this test. For eight hours before the test, the person must fast. A healthcare provider draws the first sample of blood at the end of the fast to determine the glucose level at the start of the test. The healthcare provider then gives the person a beverage containing 2.6 oz. (75g) of glucose. Two hours later, the person's blood is drawn again. These blood samples are centrifuged and processed in the laboratory. A doctor can then compare the before and after glucose levels to see how well the patient's body processed the sugar.

Two-hour postprandial blood glucose test

The two-hour postprandial blood glucose test measures the amount of glucose in plasma after a person eats a specific meal containing a certain amount of sugar. Although the meal follows a predetermined menu, it is difficult to control many factors associated with this testing method.

Blood sugar tests can be used in a variety of situations including:

- Testing people suspected for diabetes. The American Diabetic Association (ADA) recommends that either a fasting plasma glucose test or an oral glucose tolerance test be used to diagnose diabetes. If the person already has symptoms of diabetes, a blood glucose test without fasting (called a casual plasma glucose test) may be done. If the test result is abnormal, it must be confirmed with another test performed on another day. The two tests can be different or they can be the same, but they must be done on different days. If the second test also is abnormal, the person has diabetes. A two-hour postprandial test is not recommended by the ADA as a test to use for the diagnosis of diabetes. A doctor may order this test, and follow it with the oral glucose tolerance test or the fasting plasma glucose test if the results are abnormal.
- Testing pregnant women. Diabetes that occurs during pregnancy (gestational diabetes) is dangerous for both the mother and the baby. Women who may be at risk are screened when they are 24–28 weeks pregnant. A woman is considered at risk if she is older than 25 years, is not at her normal body weight, has a parent or sibling with diabetes, or if she is in an ethnic group that has a high rate of diabetes (Hispanics, Native Americans, Asians, African Americans). The blood sugar test to screen for gestational diabetes is a variation of the oral glucose tolerance test. Fasting is not required. If the result is abnormal, a more complete test is done on another day.
- Testing healthy people. Healthy people without symptoms of diabetes should be screened for diabetes when they are 45 years old and again every three years. Either the fasting plasma glucose or oral glucose tolerance test is used for screening. People in high risk groups should be tested before the age of 45 and tested more frequently.
- Testing of people already diagnosed with diabetes. The ADA recommends that a person with diabetes keep the amount of glucose in the blood at a normal level as much as possible. This can be done by the diabetic person testing his or her own blood at home one or more times a day.

Preparation

Each blood sugar test that uses plasma requires a 5 mL blood sample. A healthcare worker ties a tight band (tourniquet) on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into the vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

When fasting is required, the person should have nothing to eat or drink (except water) for eight hours before the test and until the test or series of tests is completed. The person should not smoke before or during the testing period because this can

temporarily increase the amount of glucose in the blood. Other factors that can cause inaccurate results are a change in diet before the test, illness or surgery two weeks before the test, certain drugs, and extended bed rest. The doctor may tell a person on insulin or taking pills for diabetes to stop the medication until after the test.

Aftercare

After the test or series of tests is completed (and with the approval of his or her doctor), the person should eat, drink, and take any medications that were stopped for the test.

The patient may feel discomfort when blood is drawn from a vein. Bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops will reduce bruising. Warm packs to the puncture site will relieve discomfort.

Risks

If the person experiences weakness, **fainting**, sweating, or any other unusual reaction while fasting or during the test, he or she should immediately tell the person giving the test.

Results

Normal results are:

- fasting plasma glucose test less than 120 mg/dL
- oral glucose tolerance test, 2 hours less than 140 mg/dL

For the diabetic person, the ADA recommends an ongoing blood sugar goal of less than or equal to 120 mg/dL.

Abnormal results

These abnormal results indicate diabetes and must be confirmed with repeat testing:

- fasting plasma glucose test less than or equal to 126 mg/dL
- oral glucose tolerance test, 2 hours less than or equal to 200 mg/dL
- casual plasma glucose test (nonfasting, with symptoms) less than or equal to 200 mg/dL
- gestational oral glucose tolerance test, 1 hour less than or equal to 140 mg/dL

Brain damage can occur from glucose levels below 40 mg/dL and **coma** from levels above 470 mg/dL.

A condition known as prediabetes or impaired glucose tolerance, which may lead to type 2 diabetes, usually is indicated with a reading of 100 mg/dL. Other hormone disorders can cause both hyperglycemia and hypoglycemia. Abnormal results must be interpreted by a doctor who is aware of the person's medical condition and medical history.

Blood typing and crossmatching

Definition

Blood typing is a laboratory test done to determine a person's blood type. If the person needs a blood **transfusion**, another test called crossmatching is done after the blood is typed to find blood from a donor that the person's body will accept.

Purpose

Blood typing and crossmatching are most commonly done to make certain that a person who needs a transfusion will receive blood that matches (is compatible with) his own. People must receive blood of the same blood type; otherwise, a serious, even fatal, transfusion reaction can occur.

WWW.BOOKBAZ.IR

Prevalence of blood types in the United States, by ethnicity

O positive is the most common blood type in the United States. The prevalence of different blood types in the U.S. population is as follows:

	Caucasian	African American	Hispanic	Asian
A1	33.0%	24.0%	29.0%	27.0%
A2	7.0%	2.0%	2.0%	0.5%
B1	9.0%	18.0%	9.0%	25.0%
B2	2.0%	1.0%	1.0%	0.4%
AB1	3.0%	4.0%	2.0%	7.0%
AB2	1.0%	0.3%	0.2%	0.1%
O1	37.0%	47.0%	53.0%	39.0%
O2	8.0%	4.0%	4.0%	1.0%

SOURCE: The American Red Cross, "Learn about Blood: Blood Types." Available online at: http://www.redcrossblood.org/learn-about-blood/blood-types (accessed September 5, 2014).

(Table by PreMediaGlobal. © Cengage Learning®.)

Parents who are expecting a baby have their blood typed to diagnose and prevent hemolytic disease of the newborn (HDN), a type of anemia also known as **erythroblastosis fetalis**. Babies who have a blood type different from their mothers are at risk for developing this disease. The disease is serious with certain blood type differences, but is milder with others.

A child inherits factors or genes from each parent that determine his blood type. This fact makes blood typing useful in paternity testing. To determine whether or not the alleged father could be the true father, the blood types of the child, mother, and alleged father are compared.

Legal investigations may require typing of blood or other body fluids, such as semen or saliva, to identify persons involved in crimes or other legal matters.

Description

Blood typing and crossmatching tests are performed in a blood bank laboratory by technologists trained in blood bank and transfusion services. The tests are done on blood after it has separated into cells and serum (serum is the yellow liquid left after the blood clots.) Costs for both tests are covered by insurance when the tests are determined to be medically necessary.

Blood bank laboratories are usually located in facilities, such as those operated by the American Red Cross, that collect, process, and supply blood that is donated, as well as in facilities, such as most hospitals, that prepare blood for transfusion. These laboratories are regulated by the United States Food and Drug Administration (FDA) and are often inspected and accredited by a professional association such as the American Association of Blood Banks (AABB).

Blood typing and crossmatching tests are based on the reaction between antigens and antibodies. An antigen can be anything that causes the body to launch an attack, known as an immune response, against it. The attack begins when the body builds a special protein, called an antibody, that is uniquely designed to attack and make ineffective (neutralize) the specific antigen that caused the attack. A person's body normally does not make antibodies against its own antigens, only against antigens that are foreign to it.

A person's body contains many antigens. The antigens found on the surface of red blood cells are important because they determine a person's blood type. When red blood cells having a certain blood type antigen are mixed with serum containing antibodies against that antigen, the antibodies attack and stick to the antigen. In a test tube, this reaction is observed as the formation of clumps of cells (clumping).

When blood is typed, a person's cells and serum are mixed in a test tube with commercially prepared serum and cells. Clumping tells which antigens or antibodies are present and reveals the person's blood type. When blood is crossmatched, patient serum is mixed with cells from donated blood that might be used for transfusion. Clumping or lack of clumping in the test tube tells whether or not the blood is compatible.

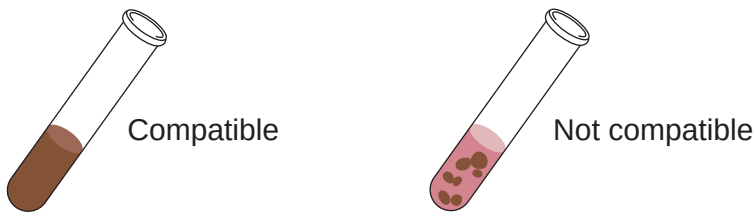
Although there are over 600 known red blood cell antigens, organized into 22 blood group systems, routine blood typing and crossmatching is usually concerned with only two systems: the ABO and Rh blood group systems.

Blood typing

ABO BLOOD GROUP SYSTEM. In 1901, Karl Landsteiner, an Austrian pathologist, randomly combined the serum and red blood cells of his colleagues. From the reactions he observed in test tubes, he discovered the ABO blood group system. This discovery earned him the 1930 Nobel Prize in Medicine.

A person's ABO blood type—A, B, AB, or O—is based on the presence or absence of the A and B antigens on his red blood cells. The A blood type has only the A antigen and the B blood type has only the B antigen. The AB blood type has both A and B antigens, and the O blood type has neither A nor B antigens.

Recipient's blood			Reactions with donor's red blood cells			
ABO antigens	ABO antibodies	ABO blood type	Donor type O cells	Donor type A cells	Donor type B cells	Donor type AB cells
None	Anti-A Anti-B	O				
A	Anti-B	A				
B	Anti-A	B				
A & B	None	AB				



Blood typing is a laboratory test done to discover a person's blood type. If the person needs a blood transfusion, crossmatching is done following blood typing to locate donor blood that the person's body will accept. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

By the time a person is six months old, he naturally will have developed antibodies against the antigens his red blood cells lack. That is, a person with A blood type will have anti-B antibodies, and a person with B blood type will have anti-A antibodies. A person with AB blood type will have neither antibody, but a person with O blood type will have both anti-A and anti-B antibodies. Although the distribution of each of the four ABO blood types varies among racial groups, O is the most common and AB is the least common.

ABO typing is the first test done on blood when it is tested for transfusion. A person must receive ABO-matched blood. ABO incompatibilities are the major cause of fatal transfusion reactions. ABO antigens are also found on most body organs, so ABO compatibility is also important for organ transplants.

An ABO incompatibility between a pregnant woman and her baby is a minor cause of HDN and usually causes no problem for the baby. The structure of ABO antibodies makes it unlikely they will cross the placenta to attack the baby's red blood cells.

Paternity testing compares the ABO blood types of the child, mother, and alleged father. The alleged father cannot be the true father if the child's blood type requires a gene that neither he nor the mother have. For example, a child with blood type B whose mother has blood type O, requires a father with either AB or B blood type; a man with blood type O cannot be the true father.

In some people, ABO antigens can be found in body fluids other than blood, such as saliva and semen. ABO typing of these fluids provides clues in legal investigations.

RH BLOOD GROUP SYSTEM. The Rh, or Rhesus, system was first detected in 1940 by Landsteiner and his colleague Alexander Wiener when they injected blood from rhesus monkeys into guinea pigs and rabbits. More than 50 antigens have since been discovered

WWW.BOOKBAZ.IR

KEY TERMS

ABO blood type—Blood type based on the presence or absence of the A and B antigens on the red blood cells.

Antibody—A special protein made by the body as a defense against foreign material that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Antigen—A toxin or other foreign substance that causes the body to launch an immune response against that antigen through the production of antibodies.

Blood bank—A laboratory that specializes in blood typing, antibody identification, and transfusion services.

Blood type—Blood categories based on the presence or absence of certain antigens on the red blood cells.

Crossmatch—A laboratory test done to confirm that blood from a donor and blood from the recipient are compatible.

Gene—A piece of DNA, located on a chromosome, that determines how traits such as blood type are inherited and expressed.

Immune response—The body's attack against an antigen that it considers foreign to itself. The attack begins with the production of antibodies against the antigen.

Rh blood type—Blood type based on the presence or absence of the D antigen on the red blood cells.

Transfusion—The therapeutic introduction of blood or a blood component into a patient's bloodstream.

belonging to this system, making it the most complex red blood cell antigen system.

In routine blood typing and crossmatching tests, only one of these 50 antigens, the D antigen, also known as the Rh factor or Rh_o[D], is tested for. If the D antigen is present, that person is Rh-positive; if the D antigen is absent, that person is Rh-negative.

Other important antigens in the Rh system are C, c, E, and e. These antigens are not usually tested for in routine blood typing tests. However, testing for the presence of these antigens is useful in paternity testing, and when a technologist tries to identify unexpected Rh antibodies or find matching blood for a person with antibodies to one or more of these antigens.

Unlike the ABO system, antibodies to Rh antigens do not develop naturally. They develop only as an immune response after a transfusion or during **pregnancy**.

The incidence of the Rh blood types varies between racial groups, but not as widely as the ABO blood types: 85% of whites and 90% of blacks are Rh-positive; 15% of whites and 10% of blacks are Rh-negative.

In transfusions, the Rh system is next in importance after the ABO system. Most Rh-negative people who receive Rh-positive blood will develop anti-D antibodies. A later transfusion of Rh-positive blood could result in a severe or fatal transfusion reaction.

Rh incompatibility is the most common and severe cause of HDN. This incompatibility can happen when an Rh-negative woman and an Rh-positive man produce an Rh-positive baby. Cells from the baby can cross the placenta and enter the mother's bloodstream, causing the mother to make anti-D antibodies. Unlike ABO antibodies, the structure of anti-D antibodies makes it likely that they will cross the placenta and enter the baby's bloodstream. There, they can destroy the baby's red blood cells, causing severe or fatal anemia.

The first step in preventing HDN is to find out the Rh types of the expectant parents. If the mother is Rh-negative and the father is Rh-positive, the baby is at risk for developing HDN. The next step is to test the mother's serum to make sure she does not already have anti-D antibodies from a previous pregnancy or transfusion. This procedure is similar to blood typing. Finally, the Rh-negative mother is given an injection of Rh Immunoglobulin (RhIg) at 28 weeks of gestation and again after delivery, if the baby is Rh positive. The RhIg attaches to any Rh-positive cells from the baby in the mother's bloodstream, preventing them from triggering anti-D antibody production in the mother. An Rh-negative woman should also receive RhIg following a **miscarriage**, abortion, or **ectopic pregnancy**.

OTHER BLOOD GROUP SYSTEMS. Several other blood group systems may be involved in HDN and transfusion reactions, although they are much less frequent than ABO and Rh. They are the Duffy, Kell, Kidd, MNS, and P systems. Tests for antigens from these systems are not included in routine blood typing, but they are commonly used in paternity testing.

Like Rh antibodies, antibodies in these systems do not develop naturally, but as an immune response after transfusion or during pregnancy. An antibody screening test is done before a crossmatch to check for unexpected antibodies to antigens in these systems. A person's serum is mixed in a test tube with commercially prepared cells containing antigens from these systems. If clumping occurs, the antibody is identified.

Crossmatching

Crossmatching is the final step in pretransfusion testing. It is commonly referred to as compatibility testing, or "Type and Cross."

Before blood from a donor and the recipient are crossmatched, both are ABO and Rh typed. In addition, antibody screening is done to look for antibodies to certain Rh, Duffy, MNS, Kell, Kidd, and P system antigens. If an antibody to one of these antigens is found, only blood without that antigen will be compatible in a crossmatch. This sequence must be repeated before each transfusion a person receives.

To begin the crossmatch, blood from a donor with the same ABO and Rh type as the rcipient is selected. In a test tube, serum from the patient is mixed with red blood cells from the donor. If clumping occurs, the blood is not compatible; if clumping does not occur, the blood is compatible. If an unexpected antibody is found in either the patient or the donor, the blood bank does further testing to make sure the blood is compatible.

In an emergency, when there is not enough time for blood typing and crossmatching, O red blood cells may be given, preferably Rh-negative. O blood type is called the universal donor because it has no ABO antigens for a patient's antibodies to attack. In contrast, AB blood type is called the universal recipient because it has no ABO antibodies to attack the antigens on transfused red blood cells. If there is time for blood typing, red blood cells of the recipient type (type specific cells) are given. In either case, the crossmatch is continued, even though the transfusion has begun.

Preparation

To collect the 10 mL blood needed for these tests, a healthcare worker ties a tourniquet above the patient's elbow, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

Blood typing and crossmatching must be done three days or less before a transfusion. A person does not need to change diet, medications, or activities before these tests. He should tell his healthcare provider if, during the last three months, he has received a blood transfusion or a plasma substitute, or has had a **radiology** procedure using intravenous contrast media. These can give false clumping reactions in both typing and crossmatching tests.

Aftercare

The possible side effects of any blood collection are discomfort or bruising at the site where the needle punctured the skin, as well as **dizziness** or **fainting**. Bruising is reduced if pressure is applied with a finger to the puncture site until the bleeding stops. Discomfort is treated with warm packs to the puncture site.

Risks

There are no risks from the blood collection or test procedures. Blood transfusions always have the risk of an unexpected transfusion reaction. A nurse watches a patient for signs of a reaction during the entire transfusion.

Results

The desired result of a crossmatch is that compatible donor blood is found. Compatibility testing procedures are designed to provide the safest blood product possible for the recipient, but a compatible crossmatch is no guarantee that an unexpected adverse reaction will not appear during the transfusion.

Except in an emergency, a person cannot receive a transfusion without a compatible crossmatch result.

Blood urea nitrogen test

Definition

Blood urea nitrogen (BUN) is a chemical waste product of protein metabolism. Proteins are broken down into amino acids within the liver; these amino acids are metabolized, giving rise to nitrogen. Nitrogen

WWW.BOOKBAZ.IR

is coupled with other molecules within the liver, producing the waste product urea that circulates in the bloodstream and goes to the kidneys. Healthy kidneys filter out this waste material from the blood. It passes into the urine and out of the body. Unhealthy kidneys, however, are unable to filter urea out of the blood. The urea remains circulating in the bloodstream, and blood urea nitrogen (BUN) levels rise as the liver continues to metabolize proteins.

The blood urea nitrogen level is used to predict how the kidneys are functioning. In many cases, the blood urea nitrogen level will begin to rise before a patient is even aware of any symptoms of kidney malfunction. High BUN levels indicate the need for further investigation into the possibility that kidney failure is ensuing. If a BUN level is elevated, then other tests such as a serum creatinine level or a 24-hour urine creatinine will be performed. Calculations involving serum and urine creatinine levels will give the creatinine clearance, a figure that reflects the capacity of the kidneys to filter small molecules out of the bloodstream.

KEY TERMS

Creatine—A substance produced from protein and stored in the muscles. Creatine is a source for energy, allowing muscle contraction to take place. Some creatine is converted to creatinine, and enters the bloodstream, where it is filtered out by healthy kidneys and leaves the body in the urine. When the kidneys are not functioning properly, creatinine levels in the blood become abnormally elevated.

Creatinine—A chemical waste product that is produced by the muscles. Creatinine enters the bloodstream and goes to the kidneys. Healthy kidneys filter out this waste material from the blood. It passes into the urine and out of the body. Unhealthy kidneys, however, are unable to filter out the creatinine from the blood. The creatinine remains circulating in the bloodstream, and levels rise as the muscles continue to produce more and more.

Urine creatinine level—A value obtained by testing a 24-hour collection of urine for the amount of creatinine present.

Purpose

A blood urea nitrogen level is usually drawn as part of a larger metabolic panel or screen. Other tests performed in this panel include electrolytes (**sodium**, potassium, chloride, and carbon dioxide), as well as **calcium**, glucose, and serum creatinine level. A blood urea nitrogen level is usually checked during a routine **physical examination**, as well as to evaluate acutely or chronically ill patients for the presence of kidney or **liver disease**, to monitor patients who have illnesses or who are taking medications that might affect the functioning of their kidneys, or to make sure that treatment for **kidney disease** (including hemodialysis or peritoneal dialysis) is effective.

Precautions

Blood urea nitrogen levels can be affected by a number of medications. Patients who are on these medications should inform their doctor, so that test results can be interpreted appropriately. Medications that may affect blood urea nitrogen levels include **diuretics**, amphotericin B, nafcillin, **aminoglycosides**, kanamycin, tobramycin, steroid medications, tetracycline **antibiotics**, and chloramphenicol. Additionally, if the blood urea nitrogen level is going to be used in calculations with serum or urine creatinine levels to evaluate kidney functioning, results may be skewed by the following medications: methyldopa, trimethoprim, vitamin C, cimetidine, certain diuretics, cephalosporin antibiotics, phenytoin, captopril, quinine, quinidine, and procainamide.

Patients who are taking anticoagulant medications should inform their healthcare practitioner since this may increase their chance of bleeding or bruising after a blood test.

Description

This test requires serum to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw serum). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The serum is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the serum draw site to stop any bleeding and decrease bruising. A bandage is then applied.

Preparation

In the 24–48 hours prior to a blood urea nitrogen level, patients should be advised to limit the amount of protein they ingest. Because urea is a waste product of

protein metabolism, ingesting more than eight ounces of meat (particularly beef) or other protein sources in the 24 hours prior to the blood urea nitrogen level is performed may affect the results.

Aftercare

As with any blood test, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a serum test, and they should be encouraged to lie down and rest until they feel better.

Risks

Basic serum tests, such as blood urea nitrogen levels, do not carry any significant risks, other than slight bruising and the chance of brief **dizziness**.

Results

A normal blood urea nitrogen level is 10–20 milligrams per deciliter (mg/dL) or 3.6–7.1 millimoles per liter (mmol/L). Women and children metabolize protein slightly differently than do men, so their BUN levels may normally be lower than those of men. BUN levels also regularly rise with age.

High levels

High blood urea nitrogen levels suggest that the kidneys are suffering from damage or disease. Kidneys can be damaged by severe infections, **shock**, cancer, **dehydration**, high blood pressure, diabetes, or conditions that limit the blood flow reaching the kidneys (such as **heart attack**, **stress**, shock, **congestive heart failure**, or severe **burns**). High blood urea nitrogen levels can also occur when the urinary tract is blocked (by a kidney stone or tumor). Other causes of increased BUN include Addison's disease, excess dietary intake of protein, bleeding in the gastrointestinal tract (resulting in the metabolism of these blood proteins generating increased urea), tissue damage that increases protein levels that reach the liver (such as may occur with very severe burns), or increases in the rate of protein metabolism in the body. BUN levels may also be elevated during a completely normal **pregnancy**.

Low levels

Low blood urea nitrogen levels are not diagnostic; however, they may reflect the presence of conditions such as **overhydration**, poor **nutrition**, liver disease, or pregnancy.

Blood-viscosity reducing drugs

Definition

Blood-viscosity reducing drugs (called hemorrheologic drugs) decrease blood thickness and stickiness by interfering with the collection of white blood cells (specifically neutrophils) in inflamed artery walls, and by helping red blood cells become more flexible so they can flow more easily through narrowed arteries. Together, these effects improve the flow of blood through arteries, as well as decreasing the risk of clots forming.

Purpose

By improving blood flow, these drugs help relieve cramps in arms, hands, and legs caused by narrowed arteries that reduce circulation and oxygen supply. **Intermittent claudication** is a condition in which **exercise** causes muscle **pain**, aches, cramps and/or numbness due to diminished blood flow. This happens when the arteries are narrowed or blocked, either by the

WWW.BOOKBAZ.IR

accumulation of plaque within the blood vessel (atherosclerosis) or by spasms in the artery walls.

These drugs are sometimes used for off-label purposes like treating **stroke**; nerve, circulation and **impotence** problems caused by diabetes; Raynaud's disease; **gangrene**; **septic shock**; complications of **sickle cell disease**; acute **alcoholic hepatitis**; and leg **ulcers**.

Description

Pentoxiphylline (Trental, Pentoxil) is the main blood-viscosity reducing drug. It is available only by prescription. This drug comes in extended-release tablet form.

Dried Ginko biloba extract reduces blood viscosity. It is available without prescription, but there are special precautions that need to be observed when using herbal medications.

Recommended dosage

The usual dosage of Trental and Pentoxil for adults is 400 mg, two to three times a day, with meals. Safety of this drug has not been established in children.

Precautions

This medicine may relieve cramps caused by poor circulation, but is not a substitute for specific treatments for underlying conditions.

This medicine may take several weeks to produce noticeable results. Be sure to keep taking it as directed, even if it does not seem to be helping.

Smoking may worsen the conditions for which the medicine is prescribed.

Older people may be especially sensitive to the effects of this medicine, which may increase the chance of side effects.

Side effects

The most common adverse effects from this drug are **nausea and vomiting**. Other, rare side effects include allergic reactions like skin rash, swelling around the lips and mouth, and headaches.

Interactions

This drug may increase the effects of theophylline (Theo-Dur). Patients also on warfarin should be monitored more closely.

Body dysmorphic disorder

Definition

Body dysmorphic disorder (BDD) is defined by the American Psychiatric Association in its *Diagnostic and Statistical Manual of Mental Disorders (DSM)* as a condition marked by excessive preoccupation with an imaginary or minor defect in a facial feature or localized part of the body. The diagnostic criteria specify that the condition must be sufficiently severe to cause a decline in the patient's social, occupational, or educational functioning. The most common cause of this decline is the time lost to obsessing about the "defect." Changes in the fifth edition of the *DSM* (*DSM-5*, 2013) include moving BDD to the category of obsessive-compulsive and related disorders. Previously, BDD was classified as a somatoform disorder—disorders characterized by physical complaints that appear to be medical in origin but that cannot be explained in terms of a physical disease, the results of substance abuse, or by another mental disorder.

Although cases of BDD have been reported in the psychiatric literature from a number of different countries for over a century, the disorder was first defined as a formal diagnostic category by the *DSM-III-R* in 1987. The word *dysmorphic* comes from two Greek words: *dys*, which means "bad" or "ugly," and *morphos,* which means "shape" or "form." BDD was previously known as dysmorphophobia.

Demographics

BDD is thought to affect 1%–2% of the population in the United States and Canada, although some doctors think that it is underdiagnosed because it coexists so often with depression and other disorders. In addition, individuals are often ashamed of grooming rituals and other behaviors associated with BDD and may avoid telling their doctor about them.

The usual age of onset of BDD is late childhood or early adolescence; the average age of individuals

diagnosed with the disorder is 17, although the disorder may develop in older individuals who become preoccupied with the physical effects of **aging**. The disorder affects men and women equally, but there are no reliable data regarding racial or ethnic differences in the incidence of the disorder. BDD has a high rate of comorbidity, which means that people diagnosed with the disorder are likely to be diagnosed with another psychiatric disorder, most commonly major depression, social phobia, or **obsessive-compulsive disorder** (OCD). About half of all men (but not women) diagnosed with BDD also have a substance abuse disorder. About 29% of individuals with BDD eventually try to commit **suicide**.

Description

BDD is characterized by an unusually exaggerated degree of worry or concern about a specific part of the face or body (such as the nose or breasts), rather than the general size or shape of the body. It is distinguished from **anorexia nervosa** and **bulimia nervosa**, where patients are preoccupied with their overall weight and body shape. Studies have found that between 40% and 76% of people with BDD seek nonpsychiatric treatments such as **cosmetic surgery** or dermatological treatments, and the rates of people with BDD among all cosmetic surgery patients range from 7% to 15%; rates are similar in dermatology practices.

Since the first publication of *DSM-IV* in 1994, some psychiatrists have suggested that a subtype of BDD exists, which they termed muscle dysmorphia. Muscle dysmorphia is marked by excessive concern with one's muscularity and/or fitness. Persons with muscle dysmorphia spend unusual amounts of time working out in gyms or exercising rather than obsessing about a feature such as the skin or nose. Muscle dysmorphia is more prevalent among males. To accommodate muscle dysmorphia as a classification, the *DSM-IV-TR* has added references regarding body build and excessive weightlifting to DSM-IV's description of BDD, and the proposed changes for *DSM-5* include muscle dysmorphia as a specifier in the diagnostic criteria for BDD. The muscle dysmorphia version of BDD is associated with higher suicide rates and higher rates of substance abuse.

BDD and muscle dysmorphia can both be described as disorders resulting from the patient's distorted **body image**. Body image refers to the mental picture individuals have of their outward appearance, including size, shape, and form. It has two major components: how people perceive their physical appearance and how they feel about their body. Significant distortions in self-perception can lead to intense body dissatisfaction and dysfunctional behaviors aimed at improving appearance. Some patients with BDD are aware that their concerns are excessive; others do not have this degree of insight. About 50% of patients diagnosed with BDD also meet the criteria for a delusional disorder, which is characterized by beliefs that are not based in reality. The *DSM-5* revised description of body dysmorphic disorder emphasizes that the individual performs repetitive behaviors such as mirror checking, skin picking, or comparing themselves to others. Learning to control these repetitive behaviors can be crucial to a BDD treatment plan.

Causes and symptoms

Causes

The causes of BDD fall into two major categories, neurobiological and psychosocial.

NEUROBIOLOGICAL CAUSES. Research indicates that patients diagnosed with BDD have serotonin levels that are lower than normal. Serotonin is a neurotransmitter—a chemical produced by the brain that helps to transmit nerve impulses across the junctions between nerve cells. Low serotonin levels are associated with depression and other **mood disorders**. However, because these studies are conducted after the person has been diagnosed with BDD, it is not possible to know whether the low serotonin levels cause the BDD or are an effect of the disorder.

PSYCHOSOCIAL CAUSES. A young person's family of origin has a powerful influence on his or her vulnerability to BDD. Children whose parents are themselves obsessed with appearance, dieting, and/or bodybuilding, or who are highly critical of their children's looks, are at greater risk of developing BDD.

An additional factor in some young people is a history of childhood **trauma** or abuse. Buried feelings about the abuse or traumatic incident emerge in the form of obsession about a part of the face or body. This "reassignment" of emotions from the unacknowledged true cause to another issue is called displacement. For example, an adolescent who frequently felt overwhelmed in childhood by physically abusive parents may develop a preoccupation with muscular strength and power.

Another important factor in the development of BDD is the influence of the mass media in developed countries, particularly the role of advertising in spreading images of supposedly physically perfect men and women. Impressionable children and adolescents absorb the message that anything short of physical

WWW.BOOKBAZ.IR

perfection is unacceptable. They may then develop distorted perceptions of their own faces and bodies.

Symptoms

The central symptom of BDD is excessive concern with a specific facial feature or body part. The parts of the body most frequently involved are the skin, hair, nose, teeth, breasts, eyes, and even eyebrows, but any feature can be a focus of the obsession.

Other symptoms of body dysmorphic disorder include:

- Ritualistic behavior. Ritualistic behavior refers to actions that the patient performs to manage anxiety and that take up excessive amounts of his or her time. Patients are typically upset if someone or something interferes with or interrupts their ritual. In the context of BDD, ritualistic behaviors may include exercise or makeup routines, assuming specific poses or postures in front of a mirror, or skin picking (dermatillomania).
- Camouflaging the "problem" feature or body part with makeup, hats, or clothing. Camouflaging appears to be the single most common symptom among persons with BDD, occurring in 94% of patients.
- Abnormal behavior around mirrors, car bumpers, large windows, or other reflective surfaces. A majority of patients diagnosed with BDD frequently check their appearance in mirrors or spend long periods of time doing so. A minority, however, react in the opposite fashion and avoid mirrors whenever possible.
- Frequently requesting reassurance from others (related to appearance).
- Frequently comparing one's appearance to others.
- Avoiding activities outside the home, including school and social events.

BDD patients have high rates of self-destructive behavior, including performing surgery on themselves at home (**liposuction** followed by skin stapling, sawing down teeth, and removing facial **scars** with sandpaper) and attempted or completed suicide. Many are unable to remain in school, form healthy relationships, or keep steady jobs. In one group of 100 patients diagnosed with BDD, 48% had been hospitalized for psychiatric reasons, and 30% had made at least one suicide attempt.

The loss of functioning resulting from BDD can have serious consequences for the patient's future. Adolescents with BDD often cut school and may be reluctant to participate in sports, join church- or civic-sponsored youth groups, or hold part-time or summer jobs. One study found that 32% of participants had missed work for at least a week in the previous month because of their BDD, while 32% of those still in school had missed classes for a week. Adults with muscle dysmorphia have been known to turn down job promotions to have more time to work out in their gym or fitness center. The economic consequences of BDD also include overspending on cosmetics, clothing, or **plastic surgery**.

Diagnosis

The diagnosis of BDD in children and adolescents is often made by physicians in family practice, as they are more likely to have developed long-term relationships of trust with the patient. With adults, it is often specialists in dermatology, **cosmetic dentistry**, or plastic surgery who may suspect that the patient has BDD because of frequent requests for repeated or unnecessary procedures. The diagnosis is made on the basis of the patient's history together with the physician's observations of the patient's overall mood and conversation patterns. People with BDD often come across to others as generally anxious and worried. In addition, the patient's dress or clothing styles, if attempting to hide the "problem" feature, may suggest a diagnosis of BDD.

Several questionnaires are used for assessing the presence of BDD. Researchers sometimes use a semi-structured interview called the BDD Data Form to collect information about the disorder from patients. This form includes demographic information, information about body areas of concern and the history and course of the illness, and the patient's history of hospitalization or suicide attempts, if any. Another diagnostic questionnaire frequently used to identify BDD patients is the Structured Clinical Interview for DSM-III-R Disorders, or SCID-II. Other questionnaires used in assessments include the Yale-Brown Obsessive Compulsive Scale Modified for Body Dysmorphic Disorder and the Body Dysmorphic Disorder Examination.

There are no brain imaging studies or laboratory tests used to diagnose BDD. Some studies using brain imaging have identified some characteristics similar to those seen in obsessive-compulsive disorder, although studies are not in complete agreement on whether these findings are diagnostic of BDD.

Treatment

The standard treatment regimen for body dysmorphic disorder is a combination of medications and **psychotherapy**. Surgical, dental, or dermatologic treatments have been found ineffective and in some cases

may exacerbate symptoms. In one study, cosmetic surgeons reported that 40% of their patients with BDD had made legal or physical threats against them.

Medications

The medications most frequently prescribed for patients with BDD are the **selective serotonin reuptake inhibitors** (SSRIs), most commonly fluoxetine (Prozac) or sertraline (Zoloft). Other SSRIs that have been used with this group of patients include fluvoxamine (Luvox) and paroxetine (Paxil). Only fluoxetine is approved by the FDA for use in children; another SSRI, escitalopram (Lexapro), is approved for use in adolescents aged 12 and up.

The relatively high rate of positive responses to SSRIs among BDD patients led to the hypothesis that the disorder has a neurobiological component related to serotonin levels in the body. An associated finding is that patients with BDD require higher dosages of SSRI medications to be effective than patients who are being treated for depression with these drugs.

According to experts at the Mayo Clinic in Rochester, Minnesota, it is important for BDD patients to continue to take their medications even when they are feeling better, because symptoms may suddenly recur. It is also important to attend psychotherapy sessions consistently.

Psychotherapy

The most effective approach to psychotherapy with BDD patients is **cognitive-behavioral therapy**, of which cognitive restructuring is one component. Because the disorder is related to **delusions** about one's appearance, cognitive-oriented therapy that challenges inaccurate self-perceptions is more effective than purely supportive approaches. Relaxation techniques also work well with BDD patients when they are combined with cognitive restructuring.

Prognosis

The *DSM-IV-TR* notes that the disorder "has a fairly continuous course, with few symptom-free intervals, although the intensity of symptoms may wax and wane over time."

Prevention

Given the pervasive influence of the mass media in contemporary Western societies, the best preventive strategy involves challenging those afflicted with the disorder and who consequently have unrealistic images of attractive people. Parents, teachers, primary healthcare professionals, and other adults who work with young people can point out and discuss the pitfalls of trying to look "perfect." In addition, parents or other adults can educate themselves about BDD and its symptoms, and should pay attention to any warning signs in their children's dress or behavior. They also can modulate their own behaviors of pointing out or highlighting physical "imperfections" in themselves or in their children, because there is a link between parents with such concerns and children with BDD.

Body image

Definition

Body image is a mental opinion or description that individuals have of their own physical appearance. It is a subjective concept, based on comparisons to socially constructed standards or ideals. Perception of body image among people can range from very negative to very positive. Depending on age and other factors, the degree of concern with body image can also vary widely among individuals.

Individuals who have a poor body image perceive their body as unattractive to others, whereas those with a good body image view their body as attractive to others. Their views may or may not accurately reflect the person's actual appearance or parallel how others judge a person's body—for instance, people may consider an individual attractive, when at the same time that individual views him- or herself as unattractive.

Description

Scientists have found that body image is first formed as an infant during contact or lack of contact with people such as parents and family members. Physical contact in the form of hugs, kisses, and other forms of affection can help develop an early positive body image. Lack of loving contact can have the opposite effect, forming an early negative body image.

Negative body image

Body image, especially among individuals as they go through **puberty** (a stage of physical and mental development that allows for sexual reproduction and causes transformation in the physical body shape), can become a problem under certain circumstances. For example, parents who are overly concerned with their children's weight and appearance may cause their children to develop negative concepts of their body. Other parents who are preoccupied with their own weight and appearance can indirectly lead their children toward being critical of their bodies. A child's peers can exert pressure, urging each other to attain a certain ideal figure or criticizing individuals who somehow do not measure up to their expectations. Media depictions of models and actors and popular discussion of celebrities in terms of their physical appearance also shape young people's perceptions about ideal body type. Body image is also closely associated with self-esteem, which is defined as the amount of value or personal worth individuals subjectively feel they have.

As puberty nears, children become increasingly focused on their physical appearance. An adolescent may mature more quickly or slowly than his or her peers. Any deviation from the perceived "ideal" can result in a negative body image, and adolescents may diet, **exercise**, or use **steroids**, stimulants, or **laxatives** to counter their own negative self-concept and achieve the body image they desire. Some teenage girls are even having **plastic surgery** (with parental permission) to "correct" what they perceive as flaws in their appearance.

Distorted body images in adolescence can lead to a number of disorders, such as **anorexia nervosa**, **bulimia nervosa**, or **body dysmorphic disorder**, a severe, clinically recognized condition characterized by an obsession with illusory body image. The behaviors that accompany these psychological disorders can be life threatening if taken to the extreme. Body image disorders are often accompanied by additional psychological problems such as depression or **anxiety** and thoughts of **suicide**. For some individuals, body image eventually becomes an all-consuming preoccupation.

Teens are especially concerned about how other people view them, and they can be more sensitive to aspects of body image and vulnerable to external pressures as they experience physiological changes. Males may be overly concerned with height when they see females of their same age who are growing taller, and females may feel sensitive about their height and weight as their bodies develop.

According to the National Eating Disorders Association, 91% of young college women report having been on at least one diet. Seventy percent of young college men report being unhappy with their body image, with 32% of all college men stating that they have dieted once or more than once. Other studies show similar percentages among young adults, which help to support the contention that young people are concerned with body image and that they generally aspire to be slim.

Differences among men and women

Concern with body image is generally more important to women than it is to men. Women usually are more critical of their overall body and individual parts of their body than are men. However, the gap between the two genders has been narrowing in the early 2000s as men become more concerned with their body image.

Poor body image is often affected by feelings of being overweight, especially with women. Men, by contrast, often desire more muscle mass when considering their body image. Their desire to be more masculine is connected to a desire to add muscle mass and

improve muscle definition. Poor body image can lead to fad dieting, **obesity**, and eating disorders, along with low self-esteem, depression, anxiety, and general emotional distress. However, for the most part, people with good exercise habits, positive personal and sexual lives, and excellent emotional and mental states have better and more accurate perceptions of their body image than people without those characteristics and experiences.

Causes and symptoms

Causes of negative body image

Body image can be affected by outside influences. Media sources, such as television, the Internet, and magazines, often portray people closer to the commonly accepted ideal body type than the average body type in order to sell their products and services. Consequently, people—especially older children and young adults—are overly influenced and swayed by such depictions of body image. According to the Association of Body Image and Disordered Eating (ABIDE), the average U.S. citizen is exposed to about 5,000 advertising messages every day. Studies of network television commercials have shown that attractiveness is a desirable trait that advertisers regularly use to convince viewers to purchase their products.

Family life can also affect a person's perception of body image. Parents who criticize their children about the way they look, talk, or act may have a negative effect on the development of self-esteem in their offspring.

Young people may also be affected by the comments of peers when it comes to their body image. Teasing conveys negative values about a person. Racial, sexual, and other types of teasing can have a negative impact on body image and self-esteem. Children may urge their peers to conform to trends in clothing, language, and other cultural aspects, all of which can potentially hurt a person's body image.

Symptoms of negative body image

Exaggerated and distorted concerns with body image have been linked in medical studies with decreases in self-esteem and increases in dieting and eating disorders, including anorexia nervosa, **binge eating disorder**, and bulimia. Bulimia is an eating disorder marked by episodes of binge eating followed by one or more behaviors to control weight, most commonly self-induced **vomiting**, laxative abuse, **fasting**, or excessive exercise. The disorder is rare in children under age 14. It is estimated to occur in between 1%–3% of high school–and college-aged women in the United States.

People with extreme body image problems may have body dysmorphic disorder (BDD), which involves a distorted body image without any eating disorders. Body dysmorphic disorder was recognized as a psychiatric disorder in 1997, although its symptoms have been exhibited in patients for more than 100 years. The disorder involves obsession and complete preoccupation with an imagined or mild physical flaw. It is known to occur in 1%–2% of Americans, but it is thought to be underdiagnosed because it often occurs in conjunction with other psychiatric disorders such as major depression and **obsessive-compulsive disorder**. Excessive preoccupation with body image and an obsession with positive body image has also been associated with the personality disorder narcissism (self-admiration or an overestimation about one's appearance).

Diagnosis

Within the field of **psychoanalysis**, a person's body image is often measured by asking individuals to rate parts of their body (such as face, stomach, and buttocks) with respect to a series of pictures representing an ideal body image. The difference in the rating between an individual's current body image and a perceived ideal body image is generally considered the amount that individuals are dissatisfied with their body.

Prevention

Without a healthy regard for one's self, people can often become very self-conscious of their body image. Feelings of depression, anxiety, and **isolation** may occur. With low self-esteem and body image problems, some people use alcohol or drugs to offset those negative feelings. Others turn away from their regular activities and their usual friends, becoming withdrawn and showing lack of interest in themselves and the world around them.

A person may recover from negative body image by attempting to accept things that cannot be changed and working on things that realistically could be improved. In some cases, outside help is needed in the form of a guidance counselor, parent, coach, religious leader, or someone else that is trusted and accepting of personal feelings. Crisis hotlines are also available to help with such problems.

Body mass index

Definition

The body mass index, or BMI, is a measurement of relative weight based on the individual's body mass divided by the square of his or her height. It is sometimes called the Quételet index, named after Lambert Adophe Quételet (1796–1874), a Belgian astronomer and statistician, who compiled it between 1830 and 1850 in order to determine the characteristics of the so-called "average person." The present term *body mass index* was coined and popularized by the American epidemiologist and nutritionist Ancel Keys (1904–2004), who first used it in a 1972 journal article prompted by the rising rates of **obesity** in the United States. Keyes considered the Quételet index to be the most accurate of the then-available indices of obesity.

Description

The BMI is a simple mathematical method for calculating the extent to which a person's body weight departs from what is considered desirable for someone of his or her height. An individual adult's BMI can be calculated in either metric units as mass (in kilograms) divided by height in meters squared, or in U.S. customary units as mass (in pounds) divided by height (in inches) squared and multiplied by 703. There are also many ready-made graphs or charts available on numerous websites that can be consulted for easy reference without the need to perform a mathematical calculation.

Different countries have somewhat different standards for interpreting the BMI depending on the average weight and height for members of their populations. For example, a person with a BMI of 23 would be considered within the normal weight range in Japan and the United States, but overweight in Hong Kong and at risk of developing **heart disease** in Singapore. The reason for these differences is that many Asian populations are at greater risk of heart disease and type 2 diabetes compared to Caucasians of the same BMI. It should be kept in mind that the BMI is used for assessing a population for overweight and obesity; its application to individuals is often controversial. The Centers for Disease Control and Prevention (CDC) lists the following guidelines for interpreting the BMIs of adults in the United States:

- Below 18.5 = underweight
- 18.5–24.9 = normal
- 25.0–29.9 = overweight
- 30–40 = obese
- 40 and above = severe obesity

The BMI for children (defined as persons below the age of 20) is calculated somewhat differently in that it takes age and sex into account as well as weight and height. The child's basic BMI is calculated in the same way as for adults, but then is evaluated as a percentile of the value for other children of the same

sex and age. A child below the fifth percentile is considered underweight for his or her age, and a child above the 95th percentile is considered obese. Children between the 85th and 95th percentiles are considered overweight.

Purpose

As noted, the BMI was devised, and is still used, to evaluate the incidence of underweight, overweight, and obesity in large population groups. In regard to individuals, it is used in several ways:

- as a screening tool to evaluate a person for possible health risks associated with overweight or underweight
- for purposes of health insurance underwriting; many private health insurers use BMI cutoff points to charge overweight people higher premiums or deny them coverage

It should be noted, however, that while the BMI is useful as a screener, it is not a diagnostic tool. While overweight and obesity are associated with a range of health problems ranging from type 2 diabetes and **coronary artery disease** to **osteoarthritis** and **sleep apnea**, a doctor must take other factors into account to determine whether a patient's overweight is a health risk. These factors include family history, evaluations of the patient's diet and level of **exercise**, and the results of blood tests.

Preparation

Calculating a BMI involves no preparation on the patientÕs part other than accurate measurement of his or her height and weight.

Aftercare

No aftercare is needed.

Results

The results are obtained by mathematical calculation and interpreted according to standard charts or tables.

Risks

The BMI is a measurement rather than a test in the strict sense. The primary risk in calculating it is misunderstanding or misuse of the results. The BMI has been criticized in recent years on the grounds that it can lead to inaccurate estimation of obesity in populations as well as individuals. The major shortcoming of the BMI (particularly in elderly groups) is that it is an indirect rather than a direct measurement of body fat. To begin with, the BMI does not make allowances for differences in bone structure; thus a person with a large frame may be classified as overweight by the BMI even though he or she has a low proportion of body fat; similarly a person with a slender frame may have a BMI in the normal range yet be carrying more body fat than is optimal. The same problem of inaccurate estimation holds true for lean body mass (muscle tissue). Athletes and others who are unusually fit may have BMIs in the overweight range even though they have relatively low levels of body fat, while people who have little lean muscle tissue may still have BMIs within the normal range.

The problem of loss of lean body tissue is particularly common in older adults, as humans tend to replace muscle tissue with fat as they age. Recent studies have indicated that many older adults in the United States and other developed countries actually have a condition called normal weight obesity, which is defined as having a body weight within the normal range but a high percentage of body fat, with the same health risks as obesity as defined by the BMI. Levels of body fat above 25% for men and 32% for women are considered to indicate obesity.

It is possible to measure a person's body fat directly, rather than indirectly as is done by the BMI. The simplest method of direct measurement is measuring the thickness of a skinfold with special calipers to obtain the amount of subcutaneous fat. Common sites on the body that are tested are the back of the upper arm, the mid-chest in front of the armpit, the abdomen, and the middle of the upper thigh. Hydrostatic weighing, or weighing the person while the person is submerged in water, is another direct method of body fat calculation, as is dual-energy x-ray absorptiometry or DXA. Hydrostatic weighing and DXA are used primarily in research, however, as they require complex equipment, bioimpedance, and skilled technicians.

In regard to health risks associated with obesity, measurements other than the BMI are considered more useful in assessing an individual's risk of type 2 diabetes and other disorders. One is the waist measurement. In the American population, a waist circumference larger than 40 inches in men and 34.5 inches in (non-pregnant) women is considered a marker of central obesity, a condition in which the person has an excessive amount of fat around the abdomen and inside the peritoneal cavity. Central obesity is a more accurate predictor than BMI of a individual's risk of heart disease and type 2 diabetes.

WWW.BOOKBAZ.IR

KEY TERMS

Central obesity—A condition in which a person has excessive amounts of fat around the waist and inside the peritoneal cavity.

Dual-energy x-ray absorptiometry (DXA)—A direct method of calculating body fat that involves scanning the patient with two x-ray beams of different energy levels. DXA is used primarily to measure bone mineral density, however, rather than percentage of body fat.

Normal weight obesity—A condition in which individuals are within the normal weight range according to their BMI but have an unacceptably high percentage of body fat.

Quételet index—The original name of the body mass index, after the Belgian statistician who devised it between 1830 and 1850.

A second measurement of central obesity is the waist/hip ratio, calculated by dividing the circumference of the waist by the circumference of the hips. A figure greater than 0.9 for men and 0.85 for women indicates central obesity.

Rebecca J. Frey, Ph.D.

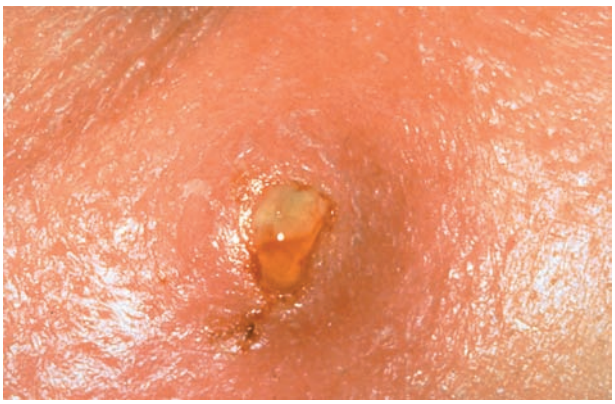
Boils

Definition

Boils and carbuncles are bacterial infections of hair follicles and surrounding skin that form pustules (small blister-like swellings containing pus) around the follicle. Boils are sometimes called furuncles. A carbuncle is formed when several furuncles merge to form a single deep **abscess** with several heads or drainage points.

Description

Boils and carbuncles are firm reddish swellings about 0.2–0.4 in. (5-10 mm) across that are slightly raised above the skin surface. They are sore to the touch. A boil usually has a visible central core of pus; a carbuncle is larger and has several visible heads. Boils occur most commonly on the face, back of the neck,



Boils often occur from a bacterial infection in a hair follicle or skin gland. *(Custom Medical Stock Photo, Inc.)*

buttocks, upper legs and groin area, armpits, and upper torso. Carbuncles are less common than single boils; they are most likely to form at the back of the neck. Males are more likely to develop carbuncles.

Boils and carbuncles are common problems in the general population, particularly among adolescents and adults. People who are more likely to develop these skin infections include those with:

- diabetes, especially when treated by injected insulin
- alcoholism or drug abuse
- poor personal hygiene
- crowded living arrangements
- jobs or hobbies that expose them to greasy or oily substances, especially petroleum products
- allergies or immune system disorders, including HIV infection.
- family members with recurrent skin infections

Causes and symptoms

Boils and carbuncles are caused by *Staphylococcus aureus*, a bacterium that causes an infection in an oil gland or hair follicle. Although the surface of human skin is usually resistant to bacterial infection, *S. aureus* can enter through a break in the skin surface—including breaks caused by needle punctures for insulin or drug injections. Hair follicles that are blocked by greasy creams, petroleum jelly, or similar products are more vulnerable to infection. Bacterial skin infections can be spread by shared cosmetics or washcloths, close human contact, or by contact with pus from a boil or carbuncle.

As the infection develops, an area of inflamed tissue gradually forms a pus-filled swelling or pimple that is painful to touch. As the boil matures, it forms a yellowish head or point. It may either continue to swell until the point bursts open and allows the pus to drain, or it may be gradually reabsorbed into the skin. It takes between one and two weeks for a boil to heal completely after it comes to a head and discharges pus. The bacteria that cause the boil can spread into other areas of the skin or even into the bloodstream if the skin around the boil is injured by squeezing. If the infection spreads, the patient will usually develop chills and **fever**, swollen lymph nodes (**lymphadenitis**), and red lines in the skin running outward from the boil.

Furunculosis is a word that is sometimes used to refer to recurrent boils. Many patients have repeated episodes of furunculosis that are difficult to treat because their nasal passages carry colonies of *S. aureus*. These bacterial colonies make it easy for the patient's skin to be reinfected. They are most likely to develop in patients with diabetes, HIV infection, or other immune system disorders.

Carbuncles are formed when the bacteria infect several hair follicles that are close together. Carbunculosis is a word that is sometimes used to refer to the development of carbuncles. The abscesses spread until they merge with each other to form a single large area of infected skin with several pus-filled heads. Patients with carbuncles may also have a low-grade fever or feel generally unwell.

Diagnosis

The diagnosis of boils and carbuncles is usually made by the patient's primary care doctor on the basis of visual examination of the skin. In some cases involving recurrent boils on the face, the doctor may need to consider **acne** as a possible diagnosis, but for the most part boils and carbuncles are not difficult to distinguish from other skin disorders.

Treatment

Patient and family education

Patient education is an important part of the treatment of boils and carbuncles. Patients need to be warned against picking at or squeezing boils because of the danger of spreading the infection into other parts of the skin or bloodstream. It is especially important to avoid squeezing boils around the mouth or nose because infections in these areas can be carried to the brain. Patients should also be advised about keeping the skin clean, washing their hands carefully before and after touching the boil or carbuncle, avoiding the use of greasy cosmetics or creams, and keeping their towels and washcloths separate from those of other family

WWW.BOOKBAZ.IR

members. Some doctors may recommend an antiseptic soap or gel for washing the infected areas.

If the patient has had several episodes of furunculosis, the doctor may examine family members or close contacts to see if they are carriers of *S. aureus*. In many cases they also need treatment for boils or carbuncles. Skin infections and reinfections involving small groups or clusters of people are being reported more frequently in the United States.

Medications

Boils are usually treated with application of antibiotic creams—usually clindamycin or polymyxin—following the application of hot compresses. The compresses help the infection to come to a head and drain.

Carbuncles and furunculosis are usually treated with oral **antibiotics** as well as antibiotic creams or ointments. The specific medications that are given are usually dicloxacillin (Dynapen) or cephalexin (Keflex). Erythromycin may be given to patients who are allergic to penicillin. The usual course of oral antibiotics is 5–10 days; however, patients with recurrent furunculosis may be given oral antibiotics for longer periods. Furunculosis is treated with a combination of dicloxacillin and rifampin (Rifadin).

Patients with bacterial colonies in their nasal passages are often given mupirocin (Bactroban) to apply directly to the lining of the nose.

Surgical treatment

Boils and carbuncles that are very large, or that are not draining, may be opened with a sterile needle or surgical knife to allow the pus to drain. The doctor will usually give the patient a local anesthetic if a knife is used; surgical treatment of boils is painful and usually leaves noticeable **scars**.

Alternatives

Naturopathic therapy

Naturopathic practitioners usually recommend changes in the patient's diet as well as applying herbal poultices to the infected area. The addition of zinc supplements and **vitamin A** to the diet is reported to be effective in treating boils. The application of a paste or poultice containing goldenseal (*Hydrastis canadensis*) root is recommended by naturopaths on the grounds that goldenseal helps to kill bacteria and reduce inflammation.

A close-up view of a carbuncle on person's back. *(John Watney/Photo Researchers, Inc.)*

Homeopathy

Homeopaths maintain that taking the proper homeopathic medication in the first stages of a boil or carbuncle will bring about early resolution of the infection and prevent pus formation. The most likely choices are *Belladonna* or *Hepar sulphuris*. If the boil has already formed, *Mercurius vivus* or *Silica* may be recommended to bring the pus to a head.

Western herbal therapies

A variety of herbal remedies can be applied topically to boils to fight infection. These include essential oils of bergamot (*Citrus bergamia*), chamomile (*Matricaria recutita*), lavender (*Lavandula officinalis*), and sage (*Salvia officinalis*), as well as tea tree oil (*Melaleuca* spp.). Herbalists also recommend washing the skin with a mixture of goldenseal and witch hazel. To fight the inflammation associated with boils, herbalists suggest marsh mallow (*Althaea officinalis*) ointment, tinctures (herbal solutions made with alcohol) of blue flag (*Iris versicolor*) or myrrh (*Commiphora molmol*), and slippery elm (*Ulmus fulva*) made into a poultice.

Prognosis

The prognosis for most boils is excellent. Some patients, however, suffer from recurrent carbuncles or furunculosis. In addition, although the spread of infection from boils is relatively unusual, there have been deaths reported from brain infections caused by squeezing boils on the upper lip or in the tissue folds at the base of the nose.

Prevention

There are some precautions that people can take to minimize the risk of developing bacterial skin infections:

KEY TERMS

Abscess—A localized collection of pus in the skin or other body tissue.

Carbuncle—A large, deep skin abscess formed by a group or cluster of boils.

Follicle—The small sac at the base of a hair shaft. The follicle lies below the skin surface.

Furunculosis—A condition in which the patient suffers from recurrent episodes of boils.

Pustule—A small raised pimple or blister-like swelling of the skin that contains pus.

- cleanse skin properly with soap and water, and take showers rather than tub baths
- do not share washcloths, towels, or facial cosmetics with others
- cut down on greasy or fatty foods and snacks
- always wash hands before touching the face
- consider using antiseptic soaps and shower gels
- consult a doctor if furunculosis is a persistent problem—it may indicate an underlying disease such as diabetes

Bone biopsy

Definition

Bone biopsy is the removal of a piece of bone for laboratory examination and analysis.

Purpose

Bone biopsy is used to distinguish between malignant tumors and benign bone disease such as **osteoporosis** and **osteomyelitis**. This test may be ordered to determine why a patient's bones ache or feel sore, or when a mass or deformity is found on an x ray, CT scan, **bone scan**, or other diagnostic imaging procedure.

Precautions

The patient's doctor and the surgeon who performs the bone biopsy must be told about any prescription and over-the-counter medications the patient is taking, and about **allergies** or reactions the patient has had to anesthetics or **pain** relievers. Special care must be taken with patients who have experienced bleeding problems.

Description

A bone biopsy involves using a special drill or other surgical instruments to remove bone from the patient's body. The procedure usually lasts about 30 minutes and may be performed in the hospital, a doctor's office, or a surgical center.

A drill biopsy is generally used to obtain a small specimen. After the skin covering the bone has been cleansed with an antiseptic and shaved, the patient is given a local anesthetic. The doctor will not begin the procedure until the anesthetic has numbed the area from which the bone is to be removed, but the patient may feel pressure or mild pain when the needle pierces the bone. The surgeon turns the needle in a half-circle to extract a sample from the core, or innermost part, of the bone. The sample is drawn into the hollow stem of the biopsy needle. The sample is then sent to a laboratory where it is examined under a microscope.

An open biopsy is used when a larger specimen is needed. After the area covering the bone has been cleansed with an antiseptic and shaved, the patient is administered a general anesthetic. After the anesthetic takes effect and the patient is unconscious, the surgeon makes an incision and removes a bone specimen. The specimen is sent to the laboratory for immediate analysis. Results of that analysis may indicate that additional surgery should be performed right away.

Preparation

No special preparation is needed for a drill biopsy, but a patient must fast for at least 12 hours before an open biopsy.

Some patients who are taking anticoagulants, **aspirin** and/or other products containing salicylates, some herbs, and **nutritional supplements** may be asked by their healthcare provider to discontinue taking the medications/products for a specified number of days prior to the procedure.

WWW.BOOKBAZ.IR

KEY TERMS

Biopsy—Removal and examination of tissue to determine if disease is present.

Osteomyelitis—An infection of the bone that is usually treated with antibiotics but sometimes requires surgery.

Osteoporosis—Thinning and loss of bone tissue.

Aftercare

Pain medication is prescribed after a biopsy, and vital signs are monitored until they return to normal. Most patients can go home in about an hour. If bone was removed from the spine, the patient may stay in the hospital overnight. Sutures may be necessary to close the biopsy site. The surgical site must be kept clean and dry for 48 hours, and the patient's doctor should be notified if any of these symptoms appear:

- fever
- headache
- pain on movement
- inflammation or pus near the biopsy site
- bleeding through the bandage at the biopsy site

Some patients may be prescribed a course of **antibiotics** after discharge from the healthcare facility. Antibiotics should be taken as prescribed and the entire course of antibiotic therapy should be completed by the patient.

Risks

Risks include bone fracture, injury to nearby tissue, and infection. Bleeding is a rare complication. Factors that increase risk include:

- stress
- obesity
- poor nutrition
- chronic illness
- some medications
- mind-altering drugs

Results

Normal bone is made up of collagen fibers and bone tissue.

Abnormal results

Bone biopsy can reveal the presence of benign disease, infection, or malignant tumors that have spread to the bone from other parts of the body.

Results of this test are considered reliable, but may be affected by a failure to obtain an adequate specimen or delayed microscopic examination or laboratory analysis.

Bone break fever *see* **Dengue fever**

Bone cancer

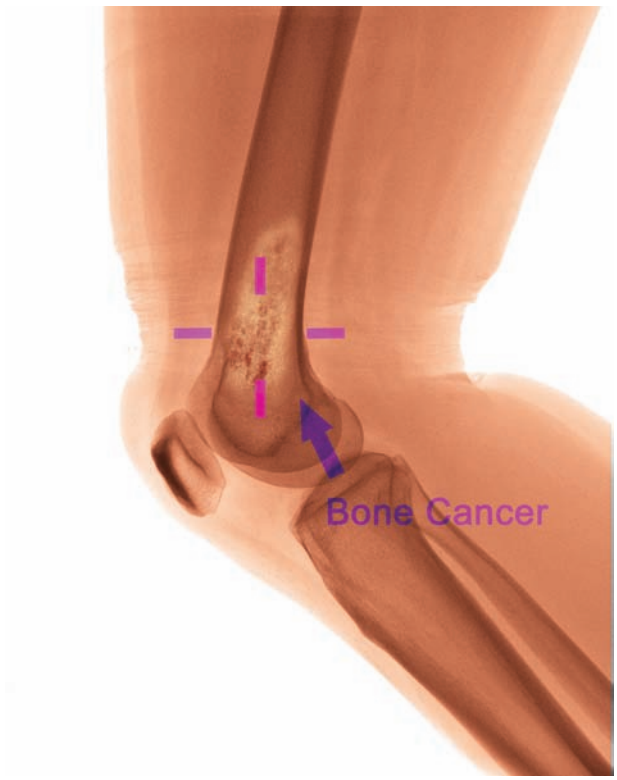
Definition

Bone cancer in this entry is defined as a primary malignant tumor of bone tissue itself, excluding 1) metastatic bone cancer, in which the bone contains metastases from primary cancers elsewhere in the body (most often cancers of the breast, prostate, or lung); and 2) benign tumors of the bone. True primary bone tumors are called **sarcomas**; they are much less common than either metastatic bone cancer or benign tumors of the bone.

Description

There are several different types of bone cancer, including soft-tissue sarcomas that begin in the bone:

- Osteosarcoma: Osteosarcoma is the most common primary bone cancer; it typically begins in the long bones of the legs, the arms, or the pelvis. It is most common in children and adolescents; however, about 10% of cases occur in adults over 60. It is more common in males than females.
- Chondrosarcoma: Chondrosarcoma is a cancer of cartilage rather than bone cells. It is the second most common type of primary bone cancer. It is usually found in adults over the age of 20 and affects



Bone cancer. *(©wonderisland/Shutterstock.com)*

women as often as men. This type of bone cancer can develop in any part of the body where there is cartilage, but is most often found in the legs, arms, and pelvis.

- Ewing sarcoma: Ewing sarcoma is named for James Ewing (1866–1943) the doctor who first described it in 1921. It is the third most common primary bone cancer and the second most common in children and young adults. Ewing sarcoma occurs most often in the pelvis, the ribs and shoulder blades, and the long bones of the arms and legs. It affects Caucasians more often than either African Americans or Asian Americans.
- Malignant fibrous histiocytoma (MFH): MFH is a very rare primary bone cancer that mostly affects middle-aged and older adults. It usually occurs in the arms or in the legs around the knees. It is also known as pleomorphic sarcoma. It should be noted, however, that some clinicians are moving away from MFH as a diagnostic category, maintaining that it originated as a catchall diagnosis for various soft-tissue tumors, and that MFH should be considered a form of fibrosarcoma.
- Fibrosarcoma: Fibrosarcoma develops more often in connective tissue than in bone itself. It occurs most often in the legs, arms, or jaw, and is diagnosed most frequently in middle-aged or elderly adults. At one time considered the most common sarcoma in adults, its incidence has declined in recent years as improved diagnostic techniques have shown that many other types of tumors mimic fibrosarcoma.
- Chordoma: Chordoma is a cancer of the bones at the base of the skull and spinal column. It occurs most often in adults over 30, and is twice as common in men as in women. Chordomas grow slowly and are less likely to metastasize to other parts of the body.

Risk factors

General risk factors for bone cancer include:

- a family history of bone cancer
- exposure to radiation therapy for a previous cancer
- Paget's disease of bone, which is a chronic but non-cancerous disorder caused by an excessive rate of bone breakdown and formation, resulting in misshapen bones, headache, arthritis, and easily fractured bones.

Some bone cancers have specific risk factors:

- Osteosarcoma: risk factors include several rare hereditary disorders: Li-Fraumeni syndrome, caused by mutations in the *p53* tumor suppressor gene and the *CHEK2* gene; Rothmund-Thomson syndrome, caused by mutations in the *REQL4* gene; and mutations in the *RB1* or retinoblastoma gene, associated with a rare hereditary form of eye cancer in children. A history of bone marrow transplantation is an additional risk factor.
- Chondrosarcoma: risk factors include multiple exostoses syndrome, a condition in which lumps of cartilage or bone develop on the bones, deforming and weakening them. The syndrome is caused by mutations in the *EXT1*, *EXT2*, or *EXT3* genes. Another condition that increases the risk of chondrosarcoma is multiple echondromatosis, a condition in which benign cartilage tumors grow into the bone.
- Ewing sarcoma: young age is the chief risk factor, as is Caucasian ethnicity.
- Malignant fibrous histiocytoma (MFH): Increased age is the chief risk factor.
- Fibrosarcoma: Increased age is the chief risk factor.
- Chordoma: In some families, mutations on chromosome 7 appear to be linked to an increased risk of chordoma. Another risk factor is tuberous sclerosis, an inherited disorder associated with mutations in the *TSC1* and *TSC2* genes.

WWW.BOOKBAZ.IR

Demographics

As noted earlier, primary bone cancers are much less common than either metastases from other cancers to the bone or benign tumors of the bone. According to the National Cancer Institute (NCI), there will be about 3,020 cases of bone cancer diagnosed in the United States in 2014, 1,680 cases in males and 1,340 cases in females. About 1,460 Americans will die of the disease, 830 males and 630 females. Bone cancer accounts for about 0.2% of all cancers in North America.

As far as is known, the rates for bone cancer are similar worldwide.

Causes and symptoms

There is no single known cause of bone cancer as of 2014. Hereditary and environmental factors are thought to be involved in addition to the uncontrolled reproduction of abnormal cells that characterizes all cancers.

Symptoms of bone cancer include:

- Pain. This is the most common single symptom of bone cancer. It may come and go at first but typically worsens over time. It may be more severe at night and disturb the patient's sleep.
- Swelling at the location of the tumor. The swelling may or may not be painful.
- Pain or stiffness in the joint closest to the tumor, and possible loss of range of motion
- Fracture in the bone affected by the tumor.
- Walking with a limp, if the leg bones are affected.
- Difficulty swallowing, if the bones in the neck are affected.
- Less common symptoms include tingling sensations or numbness when the cancer presses on the spinal nerves; weight loss and fatigue; and fever or malaise.
- Anemia (low level of red blood cells)

Diagnosis

There are no screening tests for bone cancer as of 2014; these cancers are usually diagnosed because of the symptoms they cause. The doctor will begin with the patient's and family's medical history, followed by an office examination of the affected limb and/or joints. The specific laboratory and imaging tests that will be ordered depend on the patient's age and general health; the type of bone cancer suspected; and previous test results.

Laboratory tests: The most common laboratory test ordered when bone cancer is suspected is a blood test for alkaline phosphatase (alk phos), an enzyme that appears in elevated levels in the blood when bones are growing rapidly; when a broken bone is mending; or when a bone cancer is producing abnormal bone tissue.

Imaging tests: These may include x rays, MRIs, CT scans, PET scans, angiograms (x rays of blood vessels), or scintigraphy, also known as a **bone scan**. On an x ray, a bone cancer will have a "moth-eaten" rather than a solid appearance, or it may appear as a hole in the bone. CT scans are done to determine whether the cancer has spread beyond the bones to other organs; MRI scans are particularly effective in determining the location and size of bone tumors in the spinal column. Scintigraphy is done to see whether a primary bone cancer has spread to other bones. Areas of abnormal bone will appear on a bone scan as dark gray or black "hot spots."

Biopsy: In a biopsy, a small sample of tissue is taken for examination under a microscope to confirm the diagnosis of cancer. Depending on the location of the bone tumor, the tissue sample may be taken either by a needle or by incision. In a needle biopsy, the surgeon drills a small hole in the bone and removes the sample with a needle. In an incisional biopsy, the surgeons makes a direct cut into the tumor to remove a tissue sample.

Although bone cancers can be staged according to the traditional four stages of the American Joint Commission on Cancer (AJCC) system, many surgeons simplify the staging of bone cancer into two stages: localized (AJCC Stages I, II, and III); and metastatic (AJCC Stage IV).

Treatment

Treatment of bone cancer depends on the specific type and location of the cancer.

- Surgery is the mainstay of treatment for bone cancer. The surgeon's goal is to remove as much of the tumor as possible while sparing the patient's limb whenever possible. Although amputation was almost invariably performed before the 1980s, limb-sparing surgery (also known as limb-salvage therapy) was much more common as of 2014. The surgeon may perform bone grafts or other forms of reconstructive surgery to maintain as much function as possible in the affected limb. Surgery is also done to treat fibrosarcoma and malignant fibrous histiocytoma; the surgeon will remove the cancerous tumor and a one-inch margin of healthy tissue on all sides of it. This technique is known as wide excision. The tissue that is removed

will be examined under the microscope to make sure that the outer margins are clear of cancerous cells.

- In tumors of the spinal column, wide excision may not be possible, so the surgeon may perform curettage, which involves scooping the tumor out of the bone with a spoon-shaped instrument called a curette. After removing the tumor, the surgeon will pour liquid nitrogen into the hole in the bone to kill any remaining cancer cells. This technique is called cryosurgery. After cryosurgery, the hole in the bone may be filled with a bone graft or with a liquid cement called polymethylmethyacrylate or PMMA. PMMA can be poured into the hole in the bone while liquid and allowed to harden. As it hardens, it gives off heat, which also helps to destroy remaining cancer cells.
- Radiation therapy is used to treat chondrosarcoma, which cannot be treated with chemotherapy. It may also be used to treat Ewing's sarcoma.
- Chemotherapy may be given preoperatively to patients with osteosarcoma to shrink the tumor before surgery. This approach is known as neoadjuvant therapy. Drugs used in chemotherapy for osteosarcoma include ifosfamide, epirubicin, cisplatin or carboplatin, methotrexate, doxorubicin, gemcitabine, or topotecan. Treatment of Ewing's sarcoma typically involves several weeks of chemotherapy followed by surgical removal or radiation therapy, then several more months of chemotherapy. Some drugs used to treat Ewing sarcoma are vincristine, dactinomycin, cyclophosphamide, doxorubicin, ifosfamide, and etoposide.
- Chordoma is difficult to treat with radiation therapy alone because this type of bone tumor often lies close to the brain stem and other vital structures.; it is most often treated by surgical removal of as much of the tumor as possible followed by limited doses of radiation therapy. A newer form of treatment for chordoma is targeted therapy, specifically a drug that blocks the signals from cancer genes that encourage tumors to grow. Some chordomas can be treated with imatinib (Gleevec), a medication that can be used for chordomas that have spread or recurred after treatment. Gleevec had not, however, been approved by the Food and Drug Administration (FDA) specifically to treat chordomas as of 2014, although it had been approved for the treatment of more common cancers.

Patients treated for bone cancer typically require long periods of **rehabilitation** and **physical therapy** after surgery in order to regain the full use of the affected limbs. Limb-sparing surgery may actually require longer periods of rehabilitation for the patient than **amputation** because the surgical procedures used in limb-sparing surgery are highly complex. It may take as long as a year after limb-sparing surgery on a leg for the patient to be able to walk again.

Because of the possibility of recurrence, metastasis, or a second cancer later in life, patients who have been treated for any form of bone cancer must have regular checkups and contact their doctor at the first sign of any unusual symptoms. Checkups typically include blood tests and x rays. Patients who have survived bone cancer are at increased risk of second cancers later in life.

Patients with bone cancer may also receive palliative treatment to help them manage **pain** and the side effects of cancer treatment. Palliative therapy may include nutritional counseling as well as medications to relieve nausea, **vomiting**, **diarrhea**, appetite loss, and other side effects of **chemotherapy** and **radiation therapy**.

Prognosis

The prognosis of bone cancer varies somewhat according to the specific type of cancer and the patient's age:

- Osteosarcoma: The five-year survival rate for osteosarcoma in a long bone of a limb is about 60–80% in patients who undergo chemotherapy and surgery and have no metastases. Survival rates for patients with metastases to the lungs or other bones are 15–30% even when the affected tissues are successfully removed.
- Chondrosarcoma: The 5-year survival rate is about 80%.
- Ewing's sarcoma: The 5-year survival rate for localized tumors is 70–80% after treatment with chemotherapy; the long-term survival of patients with metastatic disease is only about 10%. Factors associated with a better prognosis for Ewing's sarcoma include a smaller tumor size; patient's age below 10 years; having a tumor in an arm or leg rather than in the pelvis or chest wall; and responding well to chemotherapy.
- Malignant fibrous histiocytoma (MFH): The 5-year survival rate ranges from 35% to 60%.
- Fibrosarcoma: The 5-year survival rate is about 65%.
- Chordoma: The 10-year survival rate is about 46%

Prevention

There are no known ways to prevent bone cancer as of 2014.

WWW.BOOKBAZ.IR

KEY TERMS

Alkaline phosphatase (Alk phos)—An enzyme measurable in blood that often appears in high amounts in patients with osteosarcoma. However, many other conditions elevate the level of alkaline phosphatase.

Exostosis (plural, exostoses)—A lump that forms on the outside of a bone due to excess calcium formation. Exostoses commonly form close to joints and can cause considerable chronic pain.

Li-Fraumeni syndrome—A hereditary cancer predisposition syndrome that increases a person's risk of breast cancer, brain cancer, and osteosarcoma.

Malaise—A general feeling of unwellness.

Paget's disease of bone—A chronic but noncancerous bone disease that can result in enlarged and misshapen bones. The bones are weakened by excessive bone formation and breakdown, leading to headache, arthritis, and bones that fracture more easily than normal. It is named for Sir James Paget (1814–1899), an English surgeon and pathologist.

Retinoblastoma—A rare childhood malignant tumor of the eye.

Rothmund-Thomson syndrome—A rare disorder characterized by short stature, early hair loss, skin rashes, and noncancerous abnormalities of the bones. It is a risk factor for osteosarcoma.

Sarcoma—Any cancer that begins in bone or the soft tissues of the body, including cartilage, fat, muscle, blood vessels, or other connective or supportive tissues.

Scintigraphy—A test used in nuclear medicine to detect abnormalities in the process of bone remodeling. Also called a bone scan, the test involves injecting the patient with radioactive technetium and then scanning the body with a gamma camera. Scintigraphy should not be confused with bone density tests.

Targeted therapy—In cancer treatment, a type of drug therapy that blocks tumors by interfering with specific molecules that the cancer cells need for growth. Also called biologic therapy, targeted therapy is less harmful to normal cells than traditional chemotherapy.

Tuberous sclerosis—A rare genetic disease that causes benign tumors to grow in the brain and in other vital organs, including the kidneys, heart, eyes, lungs, and skin. It is thought to be a risk factor for chordoma.

Bone densitometry *see* **Bone density test**

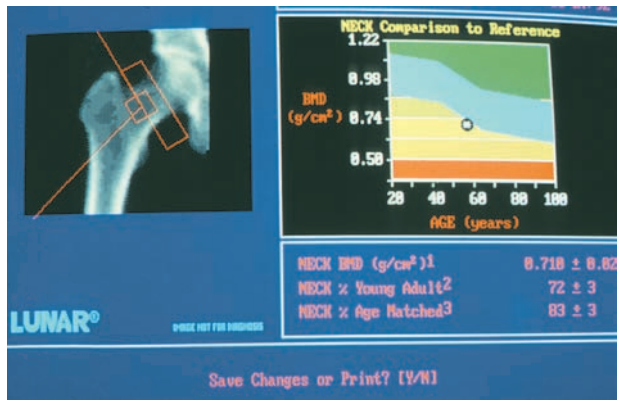
Bone density test

Definition

A bone density test, or bone density scan, is designed to check for **osteoporosis**, a disease that occurs when the bones become thin and weak. Osteoporosis occurs when the bones lose **calcium** and other **minerals** that keep them strong.

Purpose

A bone density scan measures the strength of an individual's bones and determines the risk of fracture. An observation of any osteoporosis present can be made.



Computer read-out of a bone density scan. *(Photo Researchers, Inc.)*

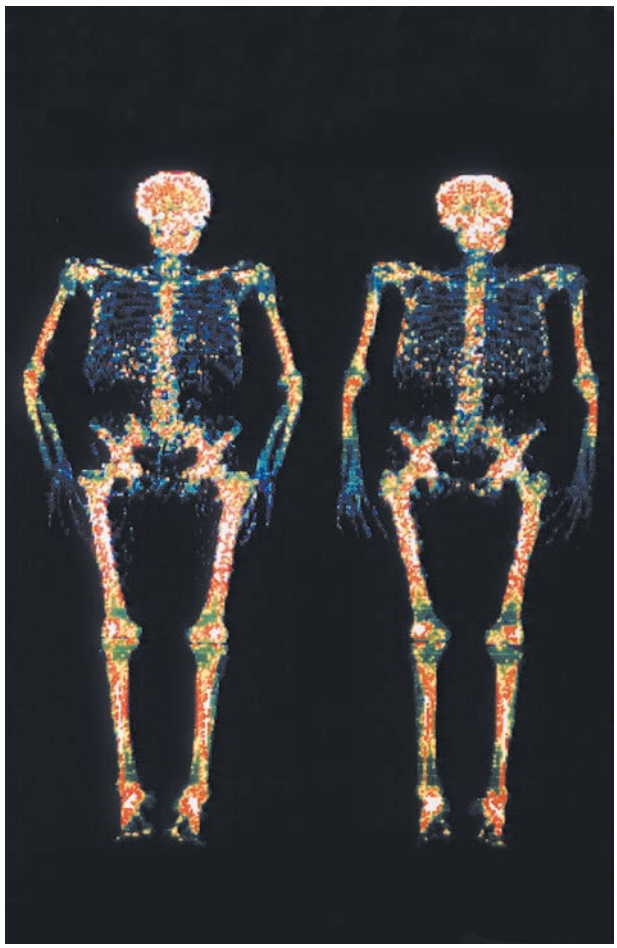
Demographics

According to the National Osteoporosis Foundation (NOF), approximately 9 million people in the United States have osteoporosis, with another 48 million at risk for developing the disease. Women are four to five times more likely than men to develop osteoporosis between ages 50 and 65. They have smaller, thinner bones than men to begin with, and they lose bone mass more rapidly after **menopause** (usually around age 50) when they stop producing the female reproductive hormone estrogen, which has a bone-protecting effect. In the five to seven years following menopause, women can lose about 20% of their bone mass. By age 65, however, men and women lose bone mass at about the same rate. About half of all of men and women over the age of 75 have osteoporosis. As an increasing number of men live to an older age, there is more awareness that osteoporosis is an important health issue for them as well as for women. Although people of any ethnic background can develop osteoporosis, it is especially common among white and Asian women over age 50.

Description

Many people are not aware that they have osteoporosis until they fracture (break) a bone. Typically, this happens in a fall that would not have caused a fracture in a young adult. Osteoporosis is estimated to be responsible for 2 million **fractures** annually. The NOF estimates that after age 50, 50% of women and 25% of men will experience an osteoporosis-related fracture. These fractures can occur in any bone, but the most common locations are the hip, spine, and wrist. Breaks in the hip and spine are of special concern because they require hospitalization and often surgery, and they commonly cause a decrease in mobility or a

WWW.BOOKBAZ.IR



A bone densitometry scan of identical twins. Their bone density is normal and identical to one another. *(Photo Researchers, Inc.)*

permanent disability. Hip fractures are a leading cause of nursing home admissions in the elderly. According to the International Osteoporosis Foundation, 33% of older adults who fracture a hip become unable to live independently, and 20% will die within 12 months.

Most bone density scans are done with a machine that uses a technology called Dual Energy X-ray Absorptiometry (DEXA). This machine takes a picture of the bones in the spine, hip, total body, and wrist and calculates the density of these bones. If a DEXA machine is not available, bone density scans can also be done with dual photon absorptiometry (measuring the spine, hip, and total body) and quantitative **computed tomography scans** (measuring the spine). Bone density scanners that use DEXA technology to just measure bone density in the wrist (called pDEXA scans) provide scans at some drugstores. These wrist scan tests are not as accurate as those that measure density in the total body, spine, or hip.

Not all doctors routinely schedule this test. Individuals may wish to ask their doctors if they need a bone density scan if they:

- are at risk for osteoporosis
- are near menopause
- have broken a bone after a modest trauma
- have a family history of osteoporosis
- use steroid or antiseizure medications
- have had a period of restricted mobility for more than six months

To take a DEXA bone density scan, the individual lies on a bed underneath the scanner, which has a curving plastic arm that emits x rays. These low-dose x rays form a fan beam that rotates around the body. During the test, the scanner moves to capture images of the individual's spine, hip, or entire body. A computer then compares the individual's bone strength and risk of fracture to that of other people in the United States of the same age and to young people at peak bone density. Bones reach peak density at about age 30 and then start to lose mass. The test takes about 20 minutes and is painless. Some insurance companies and Medicare cover the cost. pDEXA wrist bone scans in drugstores are available at little cost.

Preparation

Minimal preparation is needed. The individual may need to remove jewelry or other accessories.

Aftercare

No special aftercare is needed. The individual should be able to go home immediately without assistance after the test.

Risks

The DEXA **bone scan** exposes the individual to only a small amount of radiation—about one-fiftieth that of a **chest x ray**, or about the amount a person is exposed to from taking a cross-country airplane flight.

Results

There are two types of bone density scores: the Z-score and the T-score. The Z-score compares the patient's reading to others of the same gender and age. It is especially helpful in analyzing children and young adults who are still growing, as well as in diagnosing secondary osteoporosis.

The T-score compares a patient's reading to that of a healthy 30-year-old. The T-score is considered more

Patient undergoing a bone density scan. *(Photo Researchers, Inc.)*

KEY TERMS

Calcium—A mineral that helps build bone. After menopause, women start making less of the bone-protecting hormone estrogen and may need to increase their intake of calcium.

DEXA bone density scan—A bone density scan that uses a rotating x-ray beam to measure the strength of bones in order to determine the likelihood of fracture.

Osteoporosis—A condition found in older individuals in which bones decrease in density and become fragile and more likely to break. It can be caused by lack of vitamin D and/or calcium in the diet.

accurate in predicting fracture risk. Scores above −1 mean that an individual has a normal bone mass. Scores between −1 and −2.5 mean that the individual has low bone density, also known as osteopenia. Patients with osteopenia will not necessarily develop osteoporosis, but they should consult with their physician about ways to improve their bone health.

Abnormal results

T-scores lower than −2.5 indicate osteoporosis and identify individuals who are at a higher risk of fracture. These individuals should consult with their physician and have a repeat bone density scan every year or two.

Bone disorder drugs

Definition

Bone disorder drugs are medicines used to treat weakened, brittle bones.

Purpose

These drugs are used to treat or prevent **osteoporosis** (brittle bones) in postmenopausal women and elderly men; to treat Paget's disease, a painful, probably genetic condition associated with weak, deformed bones; and to treat both men and women who have osteoporosis from taking **corticosteroids** (prednisone) for prolonged periods of time.

Like other living tissues, bone is constantly being reabsorbed and replaced by new bone. There is normally a balance between newly forming and older bone. **Exercise** and adequate intake of **calcium** and **Vitamin D** are crucial in maintaining this balance. When bone is lost more rapidly than it is formed, the condition is initially called osteopenia. Osteoporosis is advanced bone loss.

Description

Bone disorder drugs are available only with a physician's prescription and come in tablet, nasal spray, and injectable forms.

Commonly used bone disorder drugs include bisphosphonates alendronate (Fosamax) and risedronate (Actonel); the hormone calcitonin (Miacalcin, Calcimar); and raloxifene (Evista)

Recommended dosage

Doses depend on the dosage forms and conditions being treated. Consult the prescriber or pharmacist for details.

Precautions

Aldendronate (Fosamax, Actonel)

People with low blood levels of calcium should not take this medicine. When taking the drug, it is important to have adequate amounts of calcium and Vitamin D in the diet or as dietary supplements.

People with **kidney disease** should have their renal function carefully monitored while taking this medicine.

This medicine may worsen digestive and swallowing problems. It is important to take the medicine with a full glass of water and not lie down for at least 45 minutes afterward. If digestive problems worsen, the medicine may need to be discontinued.

Some patients with cancer have developed **necrosis** (death) of bone, mostly in the jaw, after taking the drug. Regular dental exams are strongly recommended.

Some patients taking this drug experience severe bone, joint, and/or muscle **pain**.

Calcitonin (Miacalcin)

Skin tests for sensitivity are frequently used before beginning treatment with this medication.

When used as a nasal spray, this drug may cause irritation and/or small sores in the nose. If this happens, it may need to be temporarily discontinued.

The injectable form of this drug has caused serious allergic reactions in some people. The nasal spray is not known to cause such reactions.

Raloxifene (Evista)

This drug increases the risk for **blood clots** and emboli to the lungs and brain. The drug should not be used in women who have a history of **heart disease** or **stroke** and should be discontinued at least three days before surgery or prolonged bed rest.

This drug has not been proven either safe or effective for postmenopausal women.

General precautions for bone disorder drugs

To keep bones strong, the body needs calcium and vitamin D. Dairy products and fatty fish such as salmon, sardines, and tuna are good sources of both calcium and vitamin D. People who are taking bone disorder drugs who do not get enough of these nutrients in their **diets** may need to take **nutritional supplements**.

It is important to have lifelong habits of performing regular weight-bearing exercises, such as walking, to develop and maintain strong bones.

KEY TERMS

Fracture—A break or crack in a bone.

Menopause—The stage in a woman's life when menstruation stops.

Osteoporosis—A condition commonly found with aging, inadequate exercise, chronic illness, or taking corticosteroids such as prednisone long term. People with osteoporosis have advanced bone loss and brittle bones that are more easily fractured.

The use of tobacco and alcohol is not recommended for people with osteopenia or osteoporosis.

Very high blood levels of calcium may interfere with the actions of these drugs.

Anyone who has had unusual reactions to bone disorder drugs in the past should let his or her physician know before taking the drugs again. The physician also should be told about any **allergies** to foods, dyes, preservatives, or other substances.

Women who are pregnant, may become pregnant, or are **breastfeeding** should check with their physicians before using these drugs.

Side effects

Aldendronate (Fosamax, Actonel)

Common side effects include **constipation**, **diarrhea**, **indigestion**, nausea, and abdominal, bone, or muscle pain. If these symptoms do not go away, the drug may need to be discontinued.

Calcitonin (Miacalcin)

The most common side effects of Miacalcin nasal spray are nasal dryness, redness, **itching**, sores, bleeding, and general discomfort. These problems should go away as the body adjusts to the medicine. But if they do not, or if they are very uncomfortable, check with a physician. Other side effects include skin rash, **headache**, **dizziness**, **fatigue**, and back and joint pain.

Injectable calcitonin may cause minor side effects such as nausea or **vomiting**; diarrhea; stomach pain; loss of appetite; flushing of the face, ears, hands, or feet; and discomfort or redness at the injection site.

Anyone who has a skin rash or **hives** after receiving a calcitonin injection should check with a physician.

Raloxifene (Evista)

Common side effects include swelling of the feet or legs, hot flashes, leg cramps, **nausea and vomiting**, headache, and skin rash.

Interactions

Aldendronate (Fosamax or Actonel)

Taking **aspirin** with these drugs may increase the chance of upset stomach. **Acetaminophen** (Tylenol) or buffered aspirin may reduce that possibility.

All foods and beverages interfere with the absorption of these drugs.

Calcitonin (Miacalcin)

Calcitonin may keep certain other drugs used to treat Paget's disease from working properly.

Raloxifene (Evista)

Raloxifene may affect blood clotting. Patients who are taking warfarin (Coumadin) should check with their physicians before taking Evista.

Bone grafting

Definition

Bone grafting is a surgical procedure that transplants new bone or places a replacement material into spaces between or around broken bone (**fractures**) or in holes in bone (defects) to repair or replace bone tissue and aid in healing diseased bones. Transplantation of new bone may use the patient's own bone tissue from another part of the body (autograft) or bone tissue from another person (allograft).

Purpose

Bone grafting is used to repair bone fractures that are extremely complex, pose a significant risk to the patient, or fail to heal properly. Bone grafting is also used to help fusion between vertebrae, correct deformities, or provide structural support for fractures of the spine. In addition to **fracture repair**, bone grafting is used to repair defects in bone caused by congenital disorders, traumatic injury, or surgery for **bone cancer**. Bone grafts are also used for facial or cranial reconstruction.

WWW.BOOKBAZ.IR

Demographics

Degenerative diseases of the spine increase with age. People over age 50 are more likely to need a bone graft if their condition requires surgery. Traumatic injuries occur most often in people 18–44 years.

Description

Bone grafts are performed by orthopedic surgeons, neurosurgeons, craniofacial surgeons, and periodontists who have specialized training in their field of expertise, including completion of additional education beyond a general medical residency. A physician becomes board certified after completing training in a specialty area, passing examinations, and meeting certification requirements. Specialty boards certify that physicians have met certain standards. Certification is voluntary, however, and not all specialists are certified.

The surgeon and his or her surgical team will perform the surgery in a hospital on an inpatient basis.

Bone tissue is a matrix-like structure primarily composed of a protein called collagen. It is strengthened by hydroxyapatite, deposits of **calcium** and phosphate salts. Four types of bone cells are located within and around this matrix. Together, these four types of cells are responsible for building the bone matrix, maintaining it, and remodeling the bone as needed. The four types of bone cells are:

- osteoblasts, which produce the bone matrix
- osteocytes, mature osteoblasts that maintain the bone
- osteoclasts, which break down and remove bone tissue
- bone-lining cells, which cover bone surfaces

Bone grafts help to repair bone defects through three specific properties:

- osteogenesis, the formation of new bone by the cells contained within the graft
- osteoinduction, a chemical process in which molecules contained within the graft (bone morphogenetic proteins, abbreviated as BMP) convert the patient's cells into cells capable of forming bone
- osteoconduction, a physical effect whereby the graft matrix configures a scaffold on which cells in the recipient form new bone

KEY TERMS

Allograft—Tissue for transplantation that is taken from another person.

Arthrodesis—Surgery that joins (or fuses) two bones together so that the joint can no longer move; it may be done on joints such as the fingers, knees, ankles, or vertebrae of the spine.

Autograft—Tissue for transplantation that is taken from the patient.

Bone morphogenetic proteins—A family of substances in human bones and blood that encourage the process of osteoinduction.

Computed tomography (CT)—An imaging technique that produces detailed pictures (scans) of anatomical structures inside the body.

Fusion—A union or joining together of materials (e.g., bone fusion).

Hydroxyapatite—A calcium phosphate complex that is the primary mineral component of bone.

Magnetic resonance imaging (MRI)—A diagnostic imaging technique that visualizes organs and structures inside the body using a magnetic field and pulses of radio-wave energy. This form of imaging detects tumors, infection, and other types of tissue disease or damage and helps diagnose conditions that affect blood flow. The area of the body being studied is positioned inside a strong magnetic field.

Morbidity—The presence of illness; a statistic that provides the rate at which an illness or abnormality occurs.

Mortality—The occurrence of death; a statistic representing death rate, i.e., the number of deaths per unit of population in any specific region, age group, disease, or other classification, usually expressed as deaths per 1,000, 10,000, or 1,000,000.

Osteoblasts—Bone cells that build new bone tissue.

Osteoclasts—Bone cells that break down and remove bone tissue.

Osteoconduction—Provision of a scaffold for the growth of new bone.

Osteocytes—Bone cells that maintain bone tissue.

Osteogenesis—Growth of new bone.

Osteoinduction—Acceleration of new bone formation by chemical means. Also refers to the process of building, healing, and remodeling bone in humans.

Vertebra—The bones that make up the back bone (spine).

The term "graft" commonly refers to an autograft or allograft. A graft made of bone from the patient's own body (e.g., hip bones or ribs) is an autograft. To obtain a piece of bone for an autograft, the patient undergoes surgery under general **anesthesia**. An incision is made over the crest of the hip bone, a piece of bone is removed, and the incision is stitched closed.

Allograft tissue is used when the available autograft material is insufficient or the size and shape of the person's own bone is limited. Bones for allografts are usually available from organs and tissues donated by healthy people who die unexpectedly. Occasionally, allograft bone may be provided by a living donor. The allograft bone tissue from the deceased donor (cadaver) has been frozen and stored in a tissue bank that provides donor screening and the processing and storage of allograft tissue for transplantation. Allograft bone is commonly used in **reconstructive surgery** of the hip, knee, and long bones, as well as cases of bone loss due to **trauma** or tumors. Using allograft tissue eliminates the need for a second operation to remove autograft bone or tendon for later transplantation. It also reduces the risk of infection or rejection of donor tissue, and safeguards against temporary **pain** and loss of function at or near the secondary site. The U.S. Food and Drug Administration (FDA) closely regulates the use of allografts and reports that the more than 5 million allografts that were distributed to surgeons for transplant between 1999 and 2009 demonstrated a high level of safety.

To place an autograft or allograft, the surgeon makes an incision in the skin over the bone defect and shapes the bone graft or replacement material to fit into it. After the graft is placed into the defect, it is held in place with pins, plates, or screws. The incision is stitched closed, and a splint or cast is often used to prevent movement of the bones while healing.

After the bone graft has been accepted by the body, the transplanted bone is slowly converted into new living bone or soft tissue, and is incorporated into the body as a functional unit.

Bone grafts for spinal fusion

In spinal surgery, especially **spinal fusion** (arthrodesis), surgeons may decide to use bone grafts to assist in

WWW.BOOKBAZ.IR

the healing and remodeling of the spine after surgery. The procedure involves fusing two vertebrae that are next to each other to provide immediate structural support for the affected segment of the spine. Spinal fusion may be used as the surgical treatment for abnormalities in the vertebrae such as curvatures, **scoliosis** or **kyphosis**, or injuries (fractures). Bone grafts may be used in spinal fusion surgery involving the middle region (lumbar) or upper region (cervical) of the spine. Cervical spinal fusion joins selected vertebrae in the neck. Acceptance and incorporation of the graft as well as formation of bone within the graft are necessary for successful fusion. Autograft is considered ideal for spinal fusion, but 5%–35% of these surgeries are not successful. Spinal fusion surgery may also be performed using metal rods, which would not require bone grafts.

Diagnosis

The surgeon performs a clinical examination and conducts tests to determine whether bone grafting is necessary. Diagnostic imaging tests determine the precise location of damage. These tests or scans include x rays, **magnetic resonance imaging** (MRI), and computed tomography (CT). They provide an image of the affected area and indicate the exact amount of damage that has occurred due to the fracture or defect.

Preparation

Orthopedic surgeries pose varying degrees of difficulty. The patient is advised about what will take place during the procedure, as well as the risks involved. A consent form is obtained before surgery.

The following activities will help the patient prepare for surgery:

- thorough physician consultation before surgery
- banking some of his or her own blood in case a transfusion is needed
- eating well to achieve good nutritional status before and after surgery
- following a recommended exercise program before and after surgery
- maintaining a positive attitude
- smoking cessation

Aftercare

Pain is normal for a few days following surgery, and pain medication may be given as needed. A urinary catheter may be placed while the patient has limited mobility.

The recovery time after bone grafts due to fractures or spinal fusion varies from one to ten days. Vigorous **exercise** may be limited for up to three months. Children heal faster than adults.

If a spinal fusion was performed, the patient may be discharged from the hospital with a back brace or cast. The family will be taught how to provide **home care** for the patient. A splint or cast prevents injury or movement while healing.

Risks

The risks for any surgical procedure requiring anesthesia include reactions to the medications, breathing problems, bleeding, infection, and blood clot formation.

Graft rejection is unlikely for autografts, but potential consequences may include:

- additional surgical and anesthesia time (typically 30 minutes per procedure) to obtain or harvest the bone for grafting
- added costs for the additional surgery
- pain and infection at the site from which the graft is taken
- the relatively small amount of bone available for grafting
- surgical complications such as infection and pain that sometimes last longer than complications associated with the primary surgery (up to two years)

Allografts also have potential risks, including:

- bone variability, because it is harvested from a variety of donors
- grafted bone may take longer to incorporate with the host bone (compared to autograft)
- graft may be less effective than an autograft
- possibility of transferring diseases to the patient
- potential rejection due to immune response complications (patient's immune system fighting against the grafted bone tissue), though risk of rejection is reduced through the use of anti-rejection drugs

Results

Most bone grafts are successful in helping bone defects to heal. The extent of recovery depends on the size of the defect and the condition of the bone surrounding the graft at the time of surgery, as well as the general health status of the patient. Severe defects take some time to heal, and may require further attention after the initial graft. Less severe bone defects should

heal completely without serious complications. Repeat surgery is sometimes required if the condition recurs or complications develop.

Bone grafts done on the face or head usually result in a normal appearance.

Morbidity and mortality rates

Although bone harvested from the patient is ideal, postoperative morbidity is sometimes associated with hip bone or fibula (part of the knee) autografts. Morbidity of allografts is usually related to the graft incorporating more slowly and less completely into the body.

Alternatives

A variety of natural and synthetic replacement materials may be used instead of bone, including collagen (the protein substance of the white fibers of the skin, bone, and connective tissue); polymers, such as silicone and some acrylics; and ceramics such as hydroxyapatite or beta-tricalcium phosphate. Adding silicone may help to increase the bioactivity of calcium phosphate and enhance incorporation of the graft. Biologically active substances that extend or replace autografts are also being investigated, including allograft cancellous chips and cortical spacers that provide bone scaffolding and demineralized bone matrix (bone with calcium removed) that promotes new bone formation.

Recombinant bone morphogenetic proteins (BMP) are strong inducers of bone growth (osteoinductive) and are shown to grow bone better than the patient's own bone, eliminating the need for bone graft harvesting. BMPs are extracted from natural tissues and produced in the laboratory to stimulate bone production in animals and humans. BMPs are still in human clinical trials but surgeons are hopeful that the use of laboratory-produced BMP will increase to aid in the generation and repair of bone without the drawbacks of allograft and autograft transplantation.

The INFUSE Bone Graft (rhBMP-2) has received FDA approval, and has demonstrated better patient outcomes than hip autografts in operation time, blood loss, hospital stay, re-operation rate, median time to return to work, and fusion rates at 6, 12, and 24 months following surgery.

Advances in tissue engineering have provided polymer-based graft substitutes with degradable, porous, three-dimensional structure. New bone may be grown on these products; the grafts then slowly dissolve, leaving only the new bone behind.

Bone growth stimulation

Definition

Bone growth stimulation is the technique of promoting bone growth in difficult-to-heal **fractures** by applying a low electrical current or **ultrasound** to the fracture.

WWW.BOOKBAZ.IR

KEY TERMS

Anode—The positive electrode to which an electromagnetic current flows.

Cathode—The negative electrode from which an electromagnetic current flows.

Purpose

Bone growth stimulation is done when satisfactory healing is not occurring naturally or when the pace of healing is too slow. This condition is called fracture nonunion, and it occurs more frequently among adults than children, in people with severe or complex fractures, and in people who smoke.

The theory behind applying an electric current to fractures to stimulate healing is based on the fact that the concave side of the bone becomes negatively charged and the convex side is positively charged. It is believed that artificially encouraging this charging with an electric current will speed healing. In 1996, the Food and Drug Administration (FDA) also approved the application of low-intensity ultrasound pulses as a treatment for fracture nonunion.

Ultrasound and electromagnetic stimulation are expensive and are used only when healing problems exist for a substantial length of time. Each method must be used for at least three to six months to be effective.

Precautions

Bone growth stimulation cannot be used if the gap between the ends of the fracture is too large.

Description

Electric stimulation can be applied either from the inside of the body (invasively) or from the outside the body (noninvasively). Ultrasound is a noninvasive procedure. The type of stimulation selected depends on the doctor's preference, the type and location of the fracture, and the patient's motivation to comply with the treatment schedule. Treatment can take anywhere from three to six months.

Invasive stimulators

Invasive electric stimulators are either fully or partially implantable. The advantage of these devices is that they apply a direct electric current to the fracture 24 hours a day. The fully implantable stimulator requires little daily attention from the patient. Patients using a semi-implanted stimulator must regulate their own treatment schedule and have to care for the external power pack. The disadvantage of implantable and semi-implantable stimulators is that their implantation is a surgical procedure.

Fully implantable direct current stimulators are installed in a hospital under general or regional **anesthesia**. Both the stimulator and the power source are implanted. The surgeon makes an incision and places a spiral-shaped cathode inside the bone. A wire leads to the power source and a small anode. The power source is a battery pack that is implanted in the nearby muscle. The body transmits electrical current to close the circuit. The incision is then closed. Once in place, the device provides continuous direct electric current for bone growth stimulation.

Partially implanted stimulators use cathode pins that are implanted at the edge of each bone that is fractured. Wires lead to the surface of the skin where a power source and the anode are located. Wires complete the circuit. The external portion of the device is held in place by a cast. This source of stimulation also runs continuously.

Noninvasive stimulators

In the noninvasive stimulator, external electromagnetic coils are placed on either side of the fracture and are held in place by a strap or cuff. Locating the coils correctly is important, and their location relative to the fracture is usually confirmed by x rays.

The coils produce a pulsating electromagnetic field. It is up to the patient to maintain the prescribed treatment schedule. Effective treatment requires stimulation anywhere from three to ten hours each day in periods of no less than one hour.

Ultrasound stimulation is the most recent treatment for stimulating bone growth. A device that generates low intensity pulses of sound is applied to the skin over the fracture. The advantage of this technique is that it is noninvasive and the period of application of the sound pulses can be as short as 20–30 minutes each day. The results of this treatment have been studied less than the effect of electromagnetic stimulation.

Preparation

Bone growth stimulation is done only when healing has failed to occur for many months. Before it is started, x rays are done of the fracture area. If the device is to be implanted, standard preoperative blood and urine tests are done. The patient may meet with an anesthesiologist to discuss any conditions that might affect the administration of anesthesia.

Aftercare

If a noninvasive, pulsating, electromagnetic field device is used, the patient must not put any **stress** or weight on the fracture until it is healed, which is a matter of months in most cases. In all lower limb fractures, regardless of the stimulation method used, the patient can not bear weight on the limb with the fracture until healing is complete. This limits the patient's mobility for many months. Patients have the responsibility of regularly making sure that the unit works and caring for external devices and the casts that hold them in place.

Risks

Noninvasive devices have few risks associated with them. The main risk associated with implantable devices is the development of infection at the site of implantation.

Results

Success in healing a fracture nonunion using bone growth stimulation depends on the type, location, and severity of the fracture and the age and general health of the patient.

Bone infection *see* **Osteomyelitis**

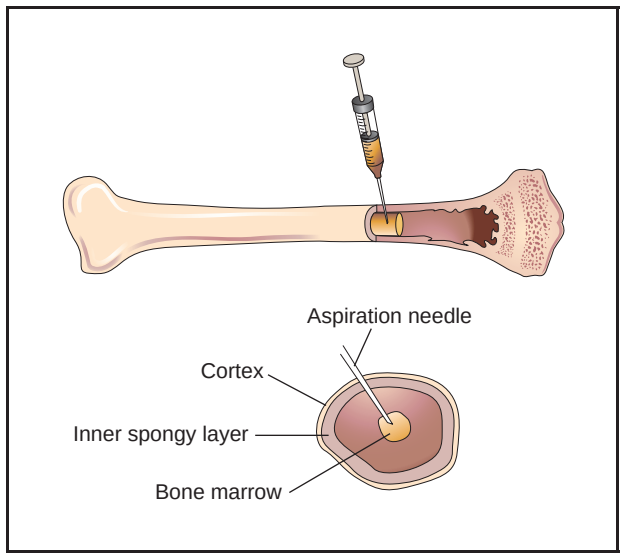
Bone marrow aspiration and biopsy

Definition

Bone marrow aspiration, also called bone marrow sampling, is the removal by suction of the soft, spongy, semisolid tissue (marrow) that fills the inside of the body's long and flat bones. Bone marrow biopsy, or needle core biopsy, is the removal of a small piece, about 0.75 x 0.06 in. (2 x 0.16 cm), of intact bone marrow. The bone marrow is where blood cells are made.

Purpose

Examination of the bone marrow may be the next step that follows an irregular clinical finding, such as an abnormal **complete blood count** (CBC), and/or an abnormal peripheral blood smear. It may also be performed following an abnormal bone image, such as the finding of a lesion on x rays.



In a bone marrow aspiration, a needle is inserted beneath the skin and rotated until it penetrates the cortex, or outer covering of the bone. A small amount of marrow is suctioned out of the bone by a syringe attached to the needle. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

A biopsy of bone marrow shows the intact tissue, so that the structure of the fat cells, lymphocytes, plasma cells, fibrous connective tissue cells, and other cells—and their relationships to each other—can be seen. A bone marrow biopsy may be used to do the following:

- diagnose and manage any form of leukemia or other myeloproliferative condition such as multiple myeloma
- rule out or confirm bone marrow infiltration by malignancies such as Hodgkin's disease, non-Hodgkin's lymphoma, and metastatic carcinoma
- monitor the effects of chemotherapy and the response or lack of response to treatment of blood disease
- evaluate the success of bone marrow transplantation
- diagnose certain genetic diseases (e.g., lipid storage disease)
- investigate pancytopenia (a decrease of all blood cells in peripheral blood), neutropenia (decreased phagocytic white blood cells), or thrombocytopenia (decreased platelets)
- diagnose an infection of unknown origin

WWW.BOOKBAZ.IR

KEY TERMS

Antibodies—Proteins that are produced normally by specialized white blood cells after stimulation by a foreign substance (antigen) and that act specifically against the antigen in an immune response.

Aspiration—A procedure to withdraw fluid and cells from the body.

Connective tissue—Cells such as fibroblasts and material such as collagen and reticulin that unite one part of the body with another.

Fibrosis—A condition characterized by the presence of scar tissue, or reticulin and collagen proliferation in tissues to the extent that it replaces normal tissues.

Hematologist—A specialist who treats diseases and disorders of the blood and blood-forming organs.

Hematoma—Blood that collects under the skin, forms a blood clot, and causes swelling.

Hemorrhage—Heavy bleeding.

Immune system—Mechanism that protects the body from foreign substances, foreign cells, and pathogens. The thymus, spleen, lymph nodes, white blood cells, including the B cells and T cells, and antibodies are involved in the immune response, which aims to destroy these foreign bodies.

Lymphocytes—Type of white blood cells that are part of the immune system. The lymphocytes are composed of three main cell lines: B lymphocytes, T lymphocytes, and natural killer (NK) cells.

Myeloma (multiple myeloma)—A tumor of plasma cells that originates in bone marrow and usually spreads to more than one bone.

Needle biopsy—The procedure of using a large hollow needle to obtain a sample of intact tissue.

Pathologist—A medical doctor who specializes in identifying diseases by studying cells and tissues under a microscope.

Plasma cells—Cells in the blood and bone marrow that are formed from B lymphocytes, and that produce antibodies.

White blood cells (leukocytes)—Cells of the blood that are responsible for fighting infection.

- investigate rare anemias for which a cause cannot be found or which does not respond to treatment as anticipated
- obtain intact bone marrow for laboratory analysis
- diagnose some types of cancer, or anemia and other blood disorders
- identify the source of an unexplained fever (e.g., granulomatous lesions)
- diagnose fibrosis of bone marrow and myeloma when bone marrow aspiration has failed to provide an appropriate specimen

The combination of aspiration and biopsy procedures are commonly used to ensure the availability of the best possible bone marrow specimen. The aspirate is collected at the same time as the bone core biopsy by attaching a syringe to the bone marrow needle and withdrawing the sample before the cutting blades are inserted and the bone core is removed. The aspirate is the sample of choice for studying and classifying the nucleated blood cells of the bone marrow (e.g., determining the ratio of immature white blood cells to red blood cells, which is the M:E ratio). The biopsy is the only sample that shows the blood-forming cells in relation to the structural and connective tissue elements (i.e., the microarchitecture) of the bone marrow. It provides the best sample for evaluating the cellularity of the bone marrow (the percentage of blood-forming tissue versus fat).

Description

A physician requests or orders the procedure. The aspirate and biopsy are most often performed in a hospital or clinic by a hematologist or pathologist that has been trained in the procedure. The analysis of the bone marrow is done by a pathologist, and a written report is added to the patient's medical record. A histologic technician performs special stains for bone marrow. Clinical laboratory scientists/medical technologists perform smear reviews and analysis of bone marrow cells by flow cytometry. Cytogenetic technologists may perform chromosomal analysis of bone marrow white blood cells.

Bone marrow aspiration and biopsy are performed by a pathologist, hematologist, or oncologist with special training in this procedure. The procedure may be performed on an outpatient basis. In adults, the specimen is usually taken from the posterior superior iliac crest (top rear part of the hip). The sternum (breastbone) may be used for aspiration, but is less desirable because it carries the risk of cardiac puncture. Other sites that are rarely used are the anterior superior iliac crest or a spinal column bone. When the

patient is a child, the biopsy site is generally the anterior tibia, the larger of the two bones in the lower leg. A vertebra may also be used.

The skin covering the biopsy site is cleansed with an antiseptic, and the patient may be given a mild sedative. A local anesthetic such as lidocaine is administered first under the skin with a fine needle and then around the bone at the intended puncture site with a somewhat larger-gauge needle. When the area is numb, a small incision is made in the skin and the biopsy needle is inserted. Pressure is applied to force the needle through the outer bone, and a decrease in resistance signals entry into the marrow cavity. The needle most often used for bone marrow biopsy is a Jamshidi trephine needle or a Westerman-Jensen trephine needle. A syringe is placed on the top of the needle and 1–2 mL of the bone marrow is aspirated into the syringe. In some instances, the marrow cannot be aspirated because it is fibrosed, or packed with neoplastic cells. The syringe is removed and the medical technologist uses this sample to prepare several smears containing small pieces of bone (spicules). Another syringe is fitted onto the needle hub and another sample of 3 mL is removed and transferred to a tube containing EDTA for analysis by flow cytometry, cytogenetic testing, or other special laboratory procedures. Following aspiration, the cutting blades are inserted into the hollow of the needle until they protrude into the marrow. The needle is then forced over the tips of the cutting blades and the needle is rotated as it is withdrawn from the bone. This process captures the core sample inside the needle. A wire probe is inserted at the cutting end, and the bone marrow sample is pushed through the hub of the needle onto sterile gauze. The specimen is used to make several preparations on glass slides or cover glasses and is transferred to a fixative solution.

In the laboratory, the aspirate slides are stained with Wright stain or Wright-Giemsa stain. The biopsy material is sectioned onto glass slides and stained with hematoxylin-eosin, Giemsa, and Prussian blue stains. Prussian blue stain is used to evaluate the amount of bone marrow iron, and the other stains are used to contrast cell structures under the microscope. In addition, special stains may be used that aid in the classification of malignant white blood cells.

Preparation

The physician should be informed of any medication the patient is using and of any heart surgery that the patient may have undergone.

Adults require no special preparation for this test. As for infants and children, they need physical and psychological preparation, depending on their age, previous medical experiences, and level of trust.

Infants

Before the test, parents should know that their child will most probably cry, and that restraints might be used. To provide comfort and to help their child through this procedure, parents are commonly asked to be present during the procedure. Crying is a normal infant response to an unfamiliar environment, strangers, restraints, and separation from the parent. Infants cry more for these reasons than because they are hurt. An infant will be restrained by hand or with devices because they have not yet developed the physical control, coordination, and ability to follow commands as adults have. The restraints used thus aim to ensure the infant's safety.

Toddlers

Parents should prepare a toddler for bone marrow aspiration directly before the procedure, because toddlers have a very short attention span. Some general guidelines for parents include the following:

- Explain the procedure in simple language, using concrete terms and avoiding abstract terminology.
- Make sure that the child understands where on the body the procedure will be performed and that it will be limited to that area.
- Allow the child to yell, cry, or express anything, especially pain, verbally.
- Describe how the test will feel.
- Stress the benefits of the procedure and anything that the child may find enjoyable afterwards, such as feeling better or going home.

Preschoolers

Parents should prepare a preschooler for bone marrow aspiration directly before the procedure, so that the child does not worry about it for days in advance. Parents should ensure that the child understands that the procedure is not a punishment. Some general guidelines for parents include the following:

- Explain the procedure in simple language, using concrete terms and avoiding abstract terminology.
- Make sure that the child understands where on the body the procedure will be performed and that it will be limited to that area.
- Allow the child to yell, cry, or express anything, especially pain, verbally.

WWW.BOOKBAZ.IR

- Describe how the test will feel and be honest about any pain that may be felt.
- Allow the child to practice different positions or movements that will be required for the procedure.
- Stress the benefits of the procedure and anything that the child may find enjoyable afterwards, such as feeling better or going for a treat on the way home.
- Practice deep breathing and other relaxation exercises. The child can also practice holding a parent's hand and squeezing it when pain is felt during the procedure.

School-age children

Explanations should be limited to 20 minutes, and repeated if required. The older the child, the earlier a parent can start preparation. Guidelines for parents include the ones provided for preschoolers, as well as the following:

- Suggest ways for maintaining control during the procedure; for example, counting, deep breathing, and relaxation (thinking pleasant thoughts).
- Include the child in the decision-making process; for example, the time of day or the body site where the procedure will be performed. These, of course, depend on the scheduling constraints of the physician and the type of procedure being performed.
- Encourage the child to participate in the procedure; for example, by holding an instrument, if allowed by the attending hospital staff.
- Encourage the child to hold a parent's hand or the hand of a nurse. Physical contact does help reduce pain and anxiety.

Adolescents

An adolescent is best prepared by being provided with detailed information and reasons for the procedure. Adolescents should be encouraged to make as many decisions as possible. An adolescent may or may not wish a parent to be present during the procedure, and such wishes should be respected, since privacy is important during adolescence. Other guidelines include the following:

- Explain the procedure in correct medical terminology, and provide the reason for it.
- As clearly as possible, describe the equipment that will be involved in concrete terms.
- Discuss potential risks honestly and openly.

Aftercare

After the needle is removed, the biopsy site is covered with a clean, dry pressure bandage. The patient must remain lying down and is observed for bleeding for one hour. The patient's pulse, breathing, blood pressure, and temperature are monitored until they return to normal. The biopsy site should be kept covered and dry for several hours.

The patient should be able to leave the clinic and resume most normal activities immediately. Patients who have received a sedative often feel sleepy for the rest of the day, so driving, cooking, and other activities that require clear thinking and quick reactions should be avoided. Walking or prescribed **pain** medications usually ease any discomfort felt at the biopsy site, and ice can be used to reduce swelling.

A doctor should be notified if the patient:

- feels severe pain for more than 24 hours after the procedure
- experiences persistent bleeding or notices more than a few drops of blood on the wound dressing
- has a temperature above 101°F (38.3°C)
- has inflammation and pus at the biopsy site or other signs of infection

Risks

A small amount of bleeding and moderate discomfort often occur at the biopsy site. Rarely, reactions to anesthetic agents, infection, and hematoma (blood clot) or hemorrhage (excessive bleeding) may also develop. In rare instances, the heart or a major blood vessel is pierced when marrow is extracted from the sternum during a bone marrow biopsy. This can lead to severe hemorrhage.

Results

Healthy adult bone marrow contains yellow fat cells, connective tissue, and red marrow that produces blood. Bone marrow is evaluated for cellularity, megakaryocyte production, M:E ratio, differential (classification of blood-forming cells), iron content, lymphoid, bone, and connective tissue cells, and bone and blood vessel abnormalities. The bone marrow of a healthy infant is primarily red (75–100% cellularity), but the distribution of blood-forming cells is very different than adult marrow. Consequently, age-related normal values must be used.

Microscopic examination of bone marrow can reveal leukemia, granulomas, **myelofibrosis**, myeloma, lymphoma, metastatic cancers, bone marrow infection, and bone disease. Bone marrow evaluation is usually not needed to diagnose anemia, but may be useful in cases that cannot be classified by other means.

Bone marrow transplantation

Definition

The bone marrow—the spongelike tissue found in the center of certain bones—contains stem cells that are the precursors of white blood cells, red blood cells, and platelets. These blood cells are vital for normal body functions, such as oxygen transport, defense against infection and disease, and clotting. Blood cells have a limited life span and are constantly being replaced; therefore, the production of healthy stem cells is vital. If a person's ability to produce these cells is compromised, a bone marrow transplant is needed.

Purpose

A person's red blood cells, white blood cells, and platelets may be abnormal due to disease, or their ability to produce these cells may be compromised. Also, certain medical therapies, particularly **chemotherapy** or **radiation therapy**, may destroy a person's stem cells. Under normal circumstances, red blood cells carry oxygen throughout the body and remove carbon dioxide from the body's tissues. White blood cells form the cornerstone of the body's immune system and defend it against infection. Platelets limit bleeding by enabling the blood to clot if a blood vessel is damaged. Problems with the function or abundance of any of these types of cells can be fatal.

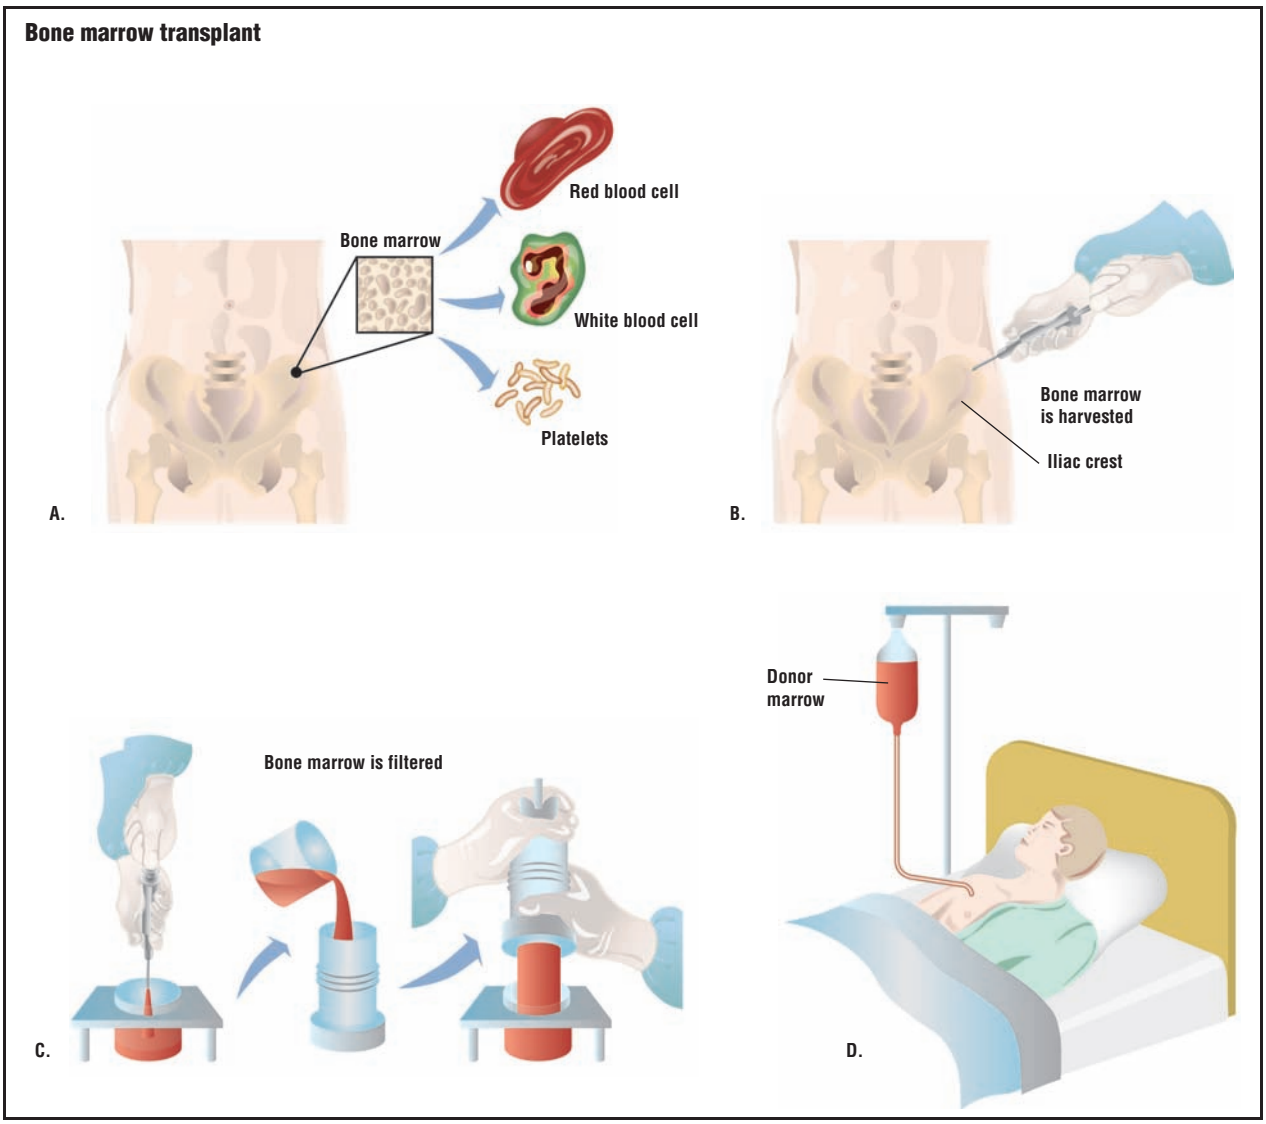
A bone marrow transplant is used to rebuild the body's capacity to produce these blood cells and bring their numbers to normal levels. Illnesses that may be treated with a bone marrow transplant include both cancerous and non-cancerous diseases.

Cancerous diseases may or may not specifically involve blood cells, but cancer treatment can destroy the body's ability to manufacture new blood cells. Bone marrow transplantation may be used in conjunction with additional treatments, such as chemotherapy, for various types of leukemia, Hodgkin's disease, lymphoma, breast and **ovarian cancer**, renal cell carcinoma, myelodysplasia, **myelofibrosis**, germ cell cancer, and other cancers. Noncancerous diseases for which bone marrow transplantation can be a treatment option include **aplastic anemia**, **sickle cell disease**, **thalassemia**, and severe **immunodeficiency**.

Demographics

The first successful bone marrow transplant took place in 1968 at the University of Minnesota. The recipient was a child with **severe combined immunodeficiency** disease and the donor was a sibling. In 1973, the first unrelated bone marrow transplant was performed at Memorial Sloan-Kettering Cancer Center in New York City on a five-year-old patient with severe combined immunodeficiency disease. In 1984, Congress passed the National Organ Transplant Act,

WWW.BOOKBAZ.IR



In a bone marrow transplant, bone marrow is harvested from the donor's pelvic bone at the iliac crest (B). The marrow is filtered (C) before being introduced into a large vein in the recipient's chest via a catheter (D). *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

which included language to evaluate unrelated marrow transplantation and determine if a national donor registry was feasible. The National Bone Marrow Donor Registry (NBMDR), now called the National Marrow Donor Program (NMDP), was established in 1986.

Bone marrow donors are always needed. At any given time, only 2% of people in the United States have listed themselves on the registry. While 7,500 recipients are seeking a genetic match, only 30% of people needing bone marrow transplants will have a matching donor within their own family. The chance of finding a match is also greatly affected by race; successful unrelated donor matches will be found for about 75% of Caucasian, 45% of Latino patients, 40% of Asian patients, and 25% of African American patients.

Description

There are three types of bone marrow transplants:

- Autologous bone marrow transplant involves the removal of an individual's bone marrow prior to the receipt of a bone marrow-destroying therapy (such as chemotherapy). The bone marrow is stored and returned to the individual at a later time. This is known as a "rescue" transplant.
- Allogeneic bone marrow transplant utilizes a donation from another individual. The donor must be a

very close genetic match to the patient, which often means that a parent or sibling is the best choice to be a donor, although bone marrow drives nationwide can sometimes reveal an unrelated donor who just happens to share genetic characteristics with the patient.

- Stem cell transplant utilizes blood cells removed and stored from a baby's umbilical cord just after birth. These cells are immature and can differentiate into the type of bone marrow cell needed with less need for careful genetic matching.

The decision to perform a bone marrow transplant is based on the patient's age, general physical condition, diagnosis, and stage of the disease. A person's age or state of health may prohibit use of a bone marrow transplant. Some centers may have age cutoffs for autologous bone marrow transplant (under age 70, generally) versus allogenic bone marrow transplant (usually under age 50). However, a person's general health is usually the more important factor. In addition, a newer technique called a mini-transplant uses doses of chemotherapy and radiation that are less toxic and can be better tolerated by older patients (sometimes up to the 70s or 80s). Before undergoing a bone marrow transplant, the bone marrow transplant team will ensure that the patient understands the potential benefits and risks of the procedure.

Autologous and allogeneic transplants

Autologous transplant is typically used in cases in which a person's bone marrow is generally healthy but will be destroyed due to medical treatment for diseases such as **breast cancer** and Hodgkin's disease. Autologous transplants are also possible if the disease affecting the bone marrow is in remission. If a person's bone marrow is unsuitable for an autologous transplant, the bone marrow must be derived from another person in an allogeneic transplant. Autologous transplants are better tolerated and have no potential for graft versus host disease, which occurs when the donor's immune cells in the bone marrow attack the tissue of the transplant recipient. Autologous transplants cannot be used when the bone marrow cells are diseased or may carry residual cancer cells.

An allogeneic bone marrow donor may be a family member or an unrelated donor. The donated bone marrow/peripheral stem cells must perfectly match the patient's bone marrow. The matching process screens potential donors' human leukocyte antigens (HLA). Antigens are markers in cells that stimulate antibody production. HLA antigens are proteins on the surface of most cells and are key molecules in generating an immune response. The HLA antigens are quite varied between individuals and represent the largest barrier to transplantation of both bone marrow and other types of organs. One set of HLA antigens is received from the father and one set from the mother. HLA testing is a series of blood tests that evaluates the closeness of tissue between the donor and recipient. If the donor and the recipient have very dissimilar antigens, the recipient's immune system regards the donor's bone marrow cells as invaders and launches a destructive attack against them. Such an attack negates any benefits offered by the transplant.

Non-myeloablative ("mini") allogeneic transplants

A "mini" transplant involves receiving low-doses of chemotherapy and radiation therapy followed by the infusion of a donor's bone marrow or peripheral stem cells. The goal is to suppress the patient's own bone marrow with low-dose chemotherapy and radiation therapy to allow the donor's cells to engraft. If there are cancer cells remaining in the patient's body, the donated cells are able to identify the cancer cells as foreign and trigger an immune response, killing the cancer cells. This is called the graft-versus-tumor effect.

Peripheral blood stem cell transplants

Peripheral blood stem cells (PBSCs) are obtained from circulating blood rather than from bone marrow, but the amount of stem cells found in the peripheral blood is much smaller than the amount of stem cells found in the bone marrow. Peripheral blood stem cells can be used in either autologous or allogeneic transplants. The majority of PBSC transplants are autologous. However, clinical studies indicate that PBSCs are being used more frequently than bone marrow for allogeneic bone marrow transplantation.

The advantages of PBSC transplants when compared to bone marrow transplants are that, in allogeneic transplantation, hematopoietic and immune recovery are faster with PBSCs. In autologous transplantation, the use of PBSCs can result in faster blood count recovery. Also, some medical conditions exist in which the recipient cannot accept bone marrow transplants, but can accept PBSC transplants. A possible disadvantage to PBSC transplant versus bone marrow transplantation is that so much more fluid volume is necessary to collect enough PBSCs that when the new stem cells are infused into the recipient, the fluid can collect in the lungs. Also, the time commitment for the donor for a PBSC transplant is considerable. When the PBSCs are being collected, several outpatient sessions are needed, and each session lasts approximately between two and four hours.

WWW.BOOKBAZ.IR

KEY TERMS

ABO antigen—Protein molecules located on the surfaces of red blood cells that determine a person's blood type: A, B, or O.

Allogeneic—Referring to bone marrow transplants between two different, genetically dissimilar people.

Antigen—A molecule that is capable of provoking an immune response.

Aplastic anemia—A disorder in which the body produces inadequate amounts of red blood cells and hemoglobin due to underdeveloped or missing bone marrow.

Autologous—Referring to bone marrow transplants in which recipients serve as their own donors.

Blast phase—Stage of chronic myelogenous leukemia in which large quantities of immature cells are produced by the marrow. This stage is not and it is not responsive to treatment.

Bone marrow—A spongy tissue located within flat bones, including the hip and breast bones and the skull. This tissue contains stem cells, the precursors of platelets, red blood cells, and white blood cells.

Bone marrow biopsy—A procedure involving the insertion of a thin needle into the breastbone or, more commonly, the hip, in order to aspirate (remove) a sample of the marrow. A small piece of cortical bone may also be obtained for examination under a microscope.

Chemotherapy—Medical treatment of a disease, particularly cancer, with drugs or other chemicals.

Chronic myelogenous leukemia (CML)—Also called chronic myelocytic leukemia, a malignant disorder that involves abnormal accumulation of white cells in the marrow and bloodstream.

Conditioning—Process of preparing a patient to receive marrow donation, often through the use of chemotherapy and radiation therapy.

Donor—A healthy person who contributes bone marrow for transplantation.

Graft versus host disease—A life-threatening complication of bone marrow transplants in which the donated marrow causes an immune reaction against the recipient's body.

Hodgkin's disease—A type of cancer involving the lymph nodes and potentially affecting non-lymphatic organs in the later stage.

Human leukocyte antigen (HLA)—A group of protein molecules located on bone marrow cells that can provoke an immune response. A donor's and a recipient's HLA types should match as closely as possible to prevent the recipient's immune system from attacking the donor's marrow as a foreign material that does not belong in the body.

Immunodeficiency—A disorder in which the immune system is ineffective or disabled due either to acquired or inherited disease.

Leukemia—A type of cancer that affects leukocytes, a particular type of white blood cell. A characteristic symptom is excessive production of immature or otherwise abnormal leukocytes.

Lymphoma—A type of cancer that affects lymph cells and tissues, including certain white blood cells (T cells and B cells), lymph nodes, bone marrow, and the spleen. Abnormal cells (lymphocyte/leukocyte) multiply uncontrollably.

Myelodysplasia—Also called myelodysplastic syndrome, a condition in which the bone marrow does not function normally and which can affect the various types of blood cells produced in the

Umbilical cord blood transplant

Umbilical cord blood transplant utilizes umbilical cord blood from a newborn as the donor source. Umbilical cord blood is rich in stem cells, the cells that are needed for transplantation. These cells are theoretically "immunologically naïve," reducing chances of rejection and making it a good source for donation. The matching criteria are the same as for bone marrow. Most programs use this procedure for a sibling or store cord blood for anonymous donation. Umbilical cord blood can be an excellent source for children. One potential problem with umbilical cord blood transplantation is the low volume of stem cells contained in the umbilical cord. In many instances, there are inadequate cell numbers to safely use for a transplant in an adult recipient.

The transplant procedure

HLA MATCHING. There are five major HLA classes or types—designated HLA-A, -B, -C, -D, and class III—but much variation within the groupings. For example, HLA-A from one individual may be similar to, but not the same as, HLA-A in another individual, which makes donor matching difficult.

bone marrow. Often referred to as a preleukemia and may progress and become acute leukemia.

Myelofibrosis—An anemic condition in which bone marrow cells are abnormal or defective and become fibrotic.

Non-myeloablative allogeneic bone marrow transplant—Also called "mini" bone marrow transplants. This type of bone marrow transplant involves receiving low-doses of chemotherapy and radiation therapy, followed by the infusion of a donor's bone marrow or peripheral stem cells. The goal is to suppress the patient's own bone marrow with low-dose chemotherapy and radiation therapy to allow the donor's cells to engraft.

Peripheral stem cells—Stem cells that are taken directly from the circulating blood and used for transplantation. Stem cells are more concentrated in the bone marrow, but they can also be extracted from the bloodstream.

Platelets—Fragments of a large precursor cell, a megakaryocyte found in the bone marrow. These fragments adhere to areas of blood vessel damage and release chemical signals that direct the formation of a blood clot.

Radiation therapy—The use of high-energy radiation from x rays, cobalt, radium, and other sources to kill cancer cells and shrink tumors. Radiation may come from a machine outside the body (external beam radiation therapy) or from materials called radioisotopes. Radioisotopes produce radiation and are placed in or near the tumor or in the area near the cancer cells. This type of radiation treatment is called internal radiation therapy, implant radiation, interstitial radiation, or brachytherapy. Systemic radiation therapy uses a radioactive substance, such as a radio-labeled monoclonal antibody that circulates throughout the body.

Recipient—The person who receives the donated blood marrow.

Red blood cells—Cells that carry hemoglobin (the molecule that transports oxygen) and help remove wastes from tissues throughout the body.

Remission—Disappearance of the signs and symptoms of cancer. When this happens, the disease is said to be "in remission." A remission can be temporary or permanent.

Sickle cell disease—An inherited disorder characterized by a genetic flaw in hemoglobin production. (Hemoglobin is the substance within red blood cells that enables them to transport oxygen.) The hemoglobin that is produced has a kink in its structure that forces the red blood cells to take on a sickle shape, inhibiting their circulation and causing pain. This disorder primarily affects people of African descent.

Stem cells—Unspecialized cells, or "immature" blood cells, that serve as the precursors of white blood cells, red blood cells, and platelets.

Thalassemia—A group of inherited disorders that affects hemoglobin production. Because hemoglobin production is impaired, a person with this disorder may suffer mild to severe anemia. Certain types of thalassemia can be fatal.

White blood cells—A group of several cell types that occur in the bloodstream and are essential for a properly functioning immune system.

HLA matching is more likely if the donor and recipient are related, particularly if they are siblings, as the siblings each carry one set of HLA genes from each parent. Therefore, a sibling has a one in four chance of being a perfect match to a patient. Sometimes an unrelated donor may be a potential match, but this is rare and requires the participation of many people in bone marrow registries. The only case in which matching HLA types between two people is not an issue is if the recipient has an identical twin. Identical twins carry the same genes and, therefore, the same antigens.

BONE MARROW HARVEST. The bone marrow extraction, or harvest, is the same for autologous and allogeneic transplants. About 30% of bone marrow harvesting involves removing bone marrow from the hip bone. This type of harvesting is done under general **anesthesia**, and discomfort is usually minimal afterwards. Bone marrow is drawn from the iliac crest (the part of the hip bone on either side of the lower back) with a special needle and a syringe. Several punctures are usually necessary to collect the needed amount of bone marrow, approximately 1–2 quarts. This amount is only a small percentage of the total bone marrow and

WWW.BOOKBAZ.IR

is typically replaced by the body within four weeks. The donor remains at the hospital for 24–48 hours and can resume normal activities within a few days.

If the bone marrow is meant for an autologous transplant, it is cryopreserved (stored at extremely cold temperatures) until it is needed. If a patient's own bone marrow can be used for transplantation or if a donor is not found, peripheral stem cells may be harvested from the patient's circulating blood. Bone marrow for an allogeneic transplant is sometimes treated to remove the donor's T cells (a type of white blood cell) or to remove ABO (blood type) antigens; otherwise, it is transplanted without modification.

The bone marrow or peripheral stem cells are administered to the recipient via a catheter (a narrow, flexible tube) inserted into a large vein in the chest. The donor cells look like a bag of blood and are infused for about 20–30 minutes. During the infusion, the patient's blood pressure, pulse, and breathing are monitored. From the bloodstream, the marrow migrates to the cavities within the bones where bone marrow is normally stored. If the transplant is successful, the bone marrow begins to produce normal blood cells once it is in place, or engrafted.

PERIPHERAL BLOOD STEM CELL TRANSPLANTATION. About 70% of bone marrow harvesting occurs using leukapheresis techniques that remove stem cells that are circulating in the bloodstream. Before collection for a PBSC transplant, donors receive five days worth of injections of the drug G-CSF, or filgrastim. Patients can give it to themselves at home, if necessary. This medication prompts immature bone marrow stem cells to move into the bloodstream. The donor's blood is then removed through an IV-type line and passes through a leukapheresis machine that retains the white blood component containing the stem cells. The rest of the blood is then returned back to the donor, and the cells are frozen for later use. Several sessions may be needed to collect an adequate number of stem cells for transplantation.

The PBSCs are administered to the recipient using the same methods as those used in bone marrow transplantation.

Costs

Bone marrow transplantation is an expensive procedure. Bone marrow donors are volunteers and do not pay for any part of the procedure. Insurance companies and health maintenance organizations (HMOs) may not cover the costs. Many insurance companies require precertification letters of medical necessity. As soon as bone marrow transplantation is discussed as a treatment option, it is important for the patient to contact his or her insurance provider to determine what costs will be covered.

Preparation

Several tests are performed before the bone marrow transplant to identify any potential problems ahead of time. Tests include:

- tissue typing and a variety of blood tests
- chest x ray
- pulmonary function tests
- computed tomography scan (CT or CAT)
- heart function tests, including an electrocardiogram and echocardiogram
- bone marrow biopsy
- skeletal survey

In addition, a complete dental exam is needed before the bone marrow transplant to reduce the risk of infection. Other precautions will be taken before the transplant to reduce the patient's risk of infection.

Frequently, a central venous catheter (a slender, hollow flexible tube) is surgically inserted into a large vein in the chest during a simple outpatient procedure. The catheter is used to draw blood and infuse chemotherapy and other medications, as well as donor cells, blood product, fluids, and sometimes nutritional solutions. The central venous catheter usually stays in place for about six months after the bone marrow transplant.

Hormone-like medications called colony-stimulating factors may be given before the transplant to stimulate the patient's white blood cells. These medications stimulate the white blood cells to multiply, mature, and function. These medications also help the patient's white blood cells recover from chemotherapy and reduce the risk of infection.

A bone marrow transplant recipient can expect to spend three to four weeks in the hospital, depending on the rate of recovery. In preparation for receiving the transplant, the recipient undergoes "conditioning," a preparative regimen (also called marrow ablation) in which the bone marrow and abnormal cells are destroyed. Conditioning rids the body of diseased cells and makes room for the marrow or peripheral stem cells to be transplanted. It typically involves chemotherapy and/or radiation treatment, depending on the disease being treated. Unfortunately, this treatment also destroys healthy cells and has many side effects such as extreme weakness, nausea, **vomiting**, and **diarrhea**. These side effects may continue for several weeks.

Aftercare

A two- to four-week waiting period follows the marrow transplant before its success can begin to be evaluated. The marrow recipient is kept in **isolation** during this time to minimize exposure to potential infections. The recipient also receives intravenous antibiotic, antiviral, and antifungal medications, as well as blood and platelet transfusions to help fight off infection and prevent excessive bleeding. Blood tests are performed daily to monitor the patient's kidney and liver function, as well as nutritional status. Other tests are performed as necessary. Further side effects, such as **nausea and vomiting**, can be treated with other medications. Once blood counts are normal and the side effects of the transplant abate, the recipient is taken off **antibiotics** and usually no longer needs blood and platelet transfusions.

Following **discharge from the hospital**, the recipient is monitored through home visits by nurses or outpatient visits for up to one year. For the first several months out of the hospital, the recipient needs to be careful in avoiding potential infections. For example, contact with other people who may be ill should be avoided or kept to a minimum. Further blood transfusions and medications may be necessary, but barring complications, the recipient can return to normal activities about six to eight months after the transplant.

Risks

The procedure has a lower success rate in older patients. Complications are exacerbated for people whose health is already seriously impaired, as in late-stage cancers.

Bone marrow transplants are accompanied by serious and life-threatening risks. Furthermore, they are not always an absolute assurance of a cure for the underlying ailment; a disease may recur in the future.

Even in the absence of complications, the transplant and associated treatments are hard on the recipient. Bone marrow transplants are debilitating. A person's ability to withstand the rigors of the transplant is a key consideration in deciding to use this treatment.

In the short term, there is the danger of **pneumonia** or other **infectious disease**, excessive bleeding, or severe gastrointestinal ailments. The transplant may be rejected by the recipient's immune system, or the donor bone marrow may launch an immune-mediated attack against the recipient's tissues. This complication is called acute graft-versus-host disease, and it can be life threatening. Characteristic signs of the disease include **fever**, rash, diarrhea, liver problems, and a compromised immune system. Methods to deplete the donated bone marrow of the T-lymphocyte cells that can cause this disease have had some success, although T-lymphocyte depletion (as it is called) can also decrease the chance of bone marrow engraftment, increasing failure rates.

Approximately 25%–50% of bone marrow transplant recipients develop long-term complications. Chronic graft-versus-host disease symptoms include skin changes, such as dryness, altered pigmentation, and thickening; abnormal **liver function tests**; **dry mouth** and eyes; infections; and weight loss. Other long-term complications include **cataracts** (due to radiation treatment), abnormal lung function, hormonal abnormalities resulting in reduced growth or **hypothyroidism**, secondary cancers, and **infertility**.

Results

In a successful bone marrow transplant, the donor's marrow migrates to the cavities in the recipient's bones and produces normal numbers of healthy blood cells. Bone marrow transplants can extend a person's life, improve quality of life, and may aid in curing the underlying ailment.

Morbidity and mortality rates

Most centers have overall survival rates of about 60% one year after bone marrow transplant; however, individual factors such as underlying disease, type of procedure, and pre-existing health conditions greatly impact the survival for the individual patient. Autologous transplants have a much better survival rate—nearly 90%—but are not appropriate for all types of ailments requiring a bone marrow transplant. Furthermore, autologous transplants have a higher failure rate with certain diseases, specifically leukemia. At two years, the survival rate for patients with chronic myelogenous leukemia is 52% if they received a transplant in a chronic phase of their disease, 30% for patients in an accelerated phase, and 15% for patients in the blast phase.

Alternatives

Complementary therapies are used along with standard cancer treatments. These treatments are aimed at bringing about some overall improvement in general health and well being. Complementary therapies can be helpful in managing symptoms and improving quality of life. They can be used to help alleviate **pain**; reduce nausea; strengthen muscles; and decrease depression, **anxiety**, and **stress**. It is important to distinguish between alternative therapies (methods promoted

WWW.BOOKBAZ.IR

for use instead of mainstream treatment) and complementary therapies, which are used in tandem with standard treatments. Complementary therapies are noninvasive and promote relaxation; however, before trying them, patients should check with their oncologist to make sure the complementary therapy will not interfere with standard cancer therapy or cause harm. Examples of complementary therapies include **massage therapy**, **aromatherapy**, **meditation**, **yoga**, **biofeedback**, music, art and dance therapies, and group or individual therapy or counseling.

Hormone therapy is the treatment of cancer by removing, blocking, or adding hormones. Hormones are chemical substances produced by glands in the body that enter the bloodstream and cause effects in other tissues. Hormone therapies may be used to treat breast and prostate cancers. Hormone therapy may also be used in some situations for other cancers.

Immunotherapy, also called biological therapy, is a type of treatment that uses the body's immune system to fight cancer. The therapy mainly consists of stimulating the immune system with highly purified proteins that help it do its job more effectively.

Radiation therapy is the use of high-energy x rays, electron beams, or radioactive isotopes to attack cancer. Radiation therapy causes cancer cell death by ionization or by damaging the chromosomes in the cancer cells so they cannot multiply. Radiation therapy is a local treatment aimed directly at the cancer. Even though the radiation is aimed only at the cancer, it must often pass through skin and other organs to reach the tumor. Thus, some healthy cells may become damaged, but the body is able to repair the healthy cells that have been damaged and restore them to their proper function. Aside from its use as a single treatment, radiation therapy has been shown to enhance the effects of chemotherapy. It can be used in combination with chemotherapy to shrink a tumor. Successful radiation therapy depends on delivering the proper amount of radiation to the cancer in the best and most effective way.

Health care team roles

Transplant physicians specially trained in bone marrow transplantation should perform this procedure. Bone marrow transplant physicians have extensive experience in hematology/oncology and bone marrow transplant.

Selecting a transplant center that has a multidisciplinary team of specialists is important. The bone marrow transplant team should include transplant physicians, infectious disease specialists, pharmacologists, registered nurses, and transplant coordinators. Other transplant team members may include registered dietitians, social workers, and financial counselors.

When selecting a transplant center, the patient should find out where the center is accredited. Some examples of accrediting organizations include the Foundation for the Accreditation of Cellular Therapy, the American Association of Blood Banks, the National Marrow Donor Program, and other state-level accrediting organizations.

Choosing a transplant center with experience is important. Questions for patients to consider when choosing a transplant center include:

- How many bone marrow transplants are performed annually, and what are the outcomes/survival rates of those transplants?
- Does the transplant center perform transplants for the patient's type of disease? How many has it performed to date?
- Does the transplant center have experience treating patients the same age as the patient considering transplant?
- What is the required patient and unrelated donor HLA matching level at this center?
- How much does a typical bone marrow transplant cost at this facility?
- Is financial help available?
- If the transplant center is far from the patient's home, will accommodations be provided for caregivers?

Bone sarcoma

Definition

Bone **sarcomas** are a type of cancers that begin in a bone.

Description

Bone sarcomas are primary bone cancers, meaning that they are cancers that begin in the bone. Cancers that begin in another area of the body, such as an organ or in the soft tissue and metastasize (spread) to a bone are not considered bone sarcomas.

There are three main types of bone sarcomas, each with different characteristics.

Osteosarcoma

Osteosarcoma is a **bone sarcoma** that begins in the osteoblast cells, which are the cells in the bone that help create new bone and give bones their strength. This type of sarcoma is most common in adolescents and is especially likely to occur during high growth periods. Because of its increased likelihood during growth spurts, it is believed that it is somehow related to increased osteoblast activity.

While osteosarcoma can begin in any bone in the body, it is most often found in the long bones of the arms and legs. It is also occasionally found to have begun in the jaw or pelvis bones. There are many different subtypes of osteosarcoma, which generally fall into three categories based on the speed of cancer growth and spread: low grade (the slowest growing), intermediate grade (somewhat faster growing than low grade), and high grade (the fastest growing osteosarcomas).

Ewing's sarcoma

Ewing's sarcoma is a rare cancer, affecting mostly children and adolescents. It begins in stem cells in the bone marrow, most commonly begins in the lower leg bones, although it also can begin in the pelvis, chest wall, arm bones, and spine. It infrequently begins in the bones of the hand or foot or in the skull. About one-quarter of patients with Ewing's sarcoma are not diagnosed until the cancer has already spread to other areas of the body.

Chondrosarcoma

Chondrosarcomas are sarcomas that begin in the cartilage. They are much more common in older adults than in children and adolescents. More than 40% of adults diagnosed with a bone sarcoma are diagnosed

WWW.BOOKBAZ.IR

with chondrosarcoma. Chondrosarcoma is a cancer of the cartilage cells. It can either grow on the surface of a bone or inside the bone itself. Although it can begin in any bone, it most frequently starts in the arm or leg bones and less frequently in the pelvis, knee, or spine.

There are a variety of subtypes of chondrosarcomas, and the majority of these cancers are relatively slow growing. Unfortunately, because the first signs of chondrosarcoma are often a dull **pain** that feels deep inside the body, it can often take 19 months or more from the time that the pain first occurs to the diagnosis of the sarcoma. The longer a cancer goes without diagnosis the more likely it is to have spread before treatment begins, which can reduce the likelihood of remission.

Demographics

Bone cancers are uncommon, making up only about 0.2% of all cancers; however, they are relatively more common in children and adolescents. According to the American Cancer Society, about 3,000 people in the United States each year are diagnosed with a **bone cancer**, and about 1,440 people die each year from bone cancer.

Osteosarcoma

Although osteosarcoma can develop at any age, it is most common in adolescents. It is the third most common type of cancer found in adolescents, and the sixth most common form of cancer found in children. About 400 people are diagnosed with osteosarcoma in the United States each year. It is slightly more common in African Americans than in Caucasians and slightly more common in males than in females. It is more likely to be diagnosed in children ages 10–19 years than in children under the age of 10.

Ewing's sarcoma

About half of patients diagnosed with Ewing's sarcoma are adolescents and about 10% of patients are between the ages 20 and 30. There are between one and three individuals diagnosed with Ewing's sarcoma per one million people each year in the United States. Overall, 27% of diagnoses occur in children younger than 10 years, 64% between age 10 and 20 years, and 9% between age 20 and 30 years. Ewing's sarcoma after age 30 is extremely rare. Ewing's sarcoma is slightly more common in males than females, and it is nine times more common in Caucasians than African Americans.

Chondrosarcoma

About 600 patients are diagnosed with chondrosarcoma in the United States each year. Chondrosarcomas are most common in older adults. The average age of a patient diagnosed with this bone sarcoma is 51 years, and it becomes more common the older the patient. Very few diagnoses of chondrosarcoma are made in younger patients; fewer than five persons in 100 diagnosed with this sarcoma is under the age of 20. Men and women are diagnosed with chondrosarcoma about equally.

Causes and symptoms

No one completely understands what causes bone sarcoma or any kind of cancer. In general, it is believed that the DNA of a cell becomes damaged or is altered when a copy is made during cell reproduction. This new, damaged DNA gives the cell instructions that make it divide much more quickly than a normal, healthy cell. These faster-growing cells begin to form a tumor and over time spread to other areas of the body where if untreated they continue to grow unchecked.

The symptoms of bone sarcomas are general, which can lead to long times from symptom onset to diagnosis. The most common symptoms include dull, aching pain in the bones, **fatigue**, and unintended weight loss. In some cases there may be swelling or the affected area may be sensitive and painful if touched.

Diagnosis

Diagnosis focuses on identifying the type and location of the cancer and how far it has spread. To do this work, the doctor uses one or more types of imaging and may perform a biopsy. The doctor also takes a **health history**, tries to identify when the first symptoms occurred, and identifies how the severity of the symptoms has progressed. The physician also tries to identify and eliminate any other explanations for the symptoms the patient is experiencing.

Imaging tests include x rays, **magnetic resonance imaging** (MRI), computerized tomography (CT), and **positron emission tomography** (PET). A specialist who is experienced in reading the relevant type of scan examines the images and determines the size, shape, location, and extent of the tumor. A complete body scan may be done to help determine if the cancer has spread beyond the point of origin to other places in the body. In some cases a biopsy may be needed.

A biopsy is a procedure during which a small sample of the tumor is removed from the body for examination. This can help determine the type of

cancer cells that are present, determine if the tumor really is cancerous (malignant), and determine how fast growing the cancer cells are. Depending on the location of the cancer, the sample can be collected using either a needle biopsy or a surgical biopsy. During a needle biopsy, a needle is used to enter through the skin and remove a sample of tissue. Many types of tumors that occur relatively near the surface of the skin can be biopsied in this way. For tumors that occur more deeply within the body, a surgical biopsy is used. During a surgical biopsy, the doctor makes a larger incision to remove a sample of the tumor. In some instances of surgical biopsy, the doctor attempts to remove the whole tumor, especially if this is likely to reduce the need for an additional surgery.

Treatment

Treatment for bone sarcomas depends on the type and location of the cancer and if and how far it has spread. The three main types of treatments (all or some of which may be used) are surgery, radiation, and **chemotherapy**.

The goal of surgery is to remove as much of the cancer as possible. This is often most helpful if the cancer is still localized in a single bone and has not spread to other areas of the body. In some cases in which the cancer occurs in an arm or leg, the best treatment option is to remove the whole limb. In other cases, surgery may be done to remove the cancer but attempt to spare the limb. When cancer occurs in non-appendage bones, such as in the ribs, surgery is performed to remove the tumor and as much of the surrounding bone or tissues as is believed necessary to completely remove the cancer.

Even after successful surgery, cancer cells may still be present. Radiation and chemotherapy are often used in combination with surgery to achieve the best outcome possible. **Radiation therapy** uses radiation to target specific areas of the body and kill cancer cells by damaging their DNA. Even though targeted, radiation therapy also kills good cells in the area that is being targeted. The most common types of radiation therapy use gamma rays, charged particles, and x rays.

Chemotherapy uses chemicals that are introduced into the body to target and kill cancer cells. There are more than 100 different kinds of medications that are used in chemotherapy, and which one is chosen depends on the type of cancer cells that are present and how far the cancer has spread. Normal cells are also often affected by chemotherapy, but in many cases, these cells can heal themselves or new healthy cells can be created, while the cancer cells die.

KEY TERMS

Chemotherapy—Medical treatment of a disease, particularly cancer, with drugs or other chemicals.

Computed tomography scan (CT scan)—A specialized type of x-ray imaging that uses highly focused and relatively low-energy radiation to produce detailed two-dimensional images of soft-tissue structures, such as the brain or abdomen. CT scans are the chief competitor to ultrasound and can yield higher-quality images not disrupted by bone or gas. They are, however, more cumbersome, time consuming, and expensive to perform, and they use ionizing radiation.

Magnetic resonance imaging (MRI)—A method for obtaining images of internal structures that uses a large circular magnet and radio waves to generate signals from atoms in the body.

Metastasis—The spread of cancer from its initial site to another part of the body.

Radiation therapy—The use of high-energy radiation from x rays, cobalt, radium, and other sources to kill cancer cells and shrink tumors. Radiation may come from a machine outside the body (external beam radiation therapy) or from materials called radioisotopes, which produce radiation and are placed in or near the tumor or in the area near the cancer cells. This type of radiation treatment is called internal radiation therapy, implant radiation, interstitial radiation, or brachytherapy. Systemic radiation therapy uses a radioactive substance, such as a radiolabeled monoclonal antibody, that circulates throughout the body.

Prognosis

The prognosis for bone sarcoma varies drastically based on the type of sarcoma and the location of its origin. Generally, bone sarcomas that originated in the arms, legs, hands, or feet have a better prognosis than those that originated in the core of the body such as the ribs. Bone sarcomas that are diagnosed while still localized have a better prognosis than those that have spread.

Osteosarcoma is believed to have a five-year survival rate of between 60% and 80% if it is diagnosed while still localized, a five-year survival rate of around 40% if the areas to which it has spread at diagnosis can be treated with surgical removal of all tumors, or if it has only spread to the lungs, and a five-year survival rate of between 15% and 30% if it has already spread to other areas at diagnosis.

Patients diagnosed with Ewing's sarcoma that is still localized at the time of diagnosis have a five-year survival

WWW.BOOKBAZ.IR

rate of nearly 70%. Patients with cancer that has already spread at the time of diagnosis have a five-year survival rate of less than 25%. Younger children have a better prognosis, with 76% of children under 15 surviving five or more years after diagnosis, and only 49% of patients aged 15 to 19 surviving the same time period.

The five year-survival rate for chondrosarcoma is estimated at between 48% and 60%. The survival rate, however, differs drastically depending on how far the cancer has spread at diagnosis. For patients who have very localized cancer at diagnosis, the five-year survival rate is estimated to be 90%. For patients who have cancer that has spread to other, distant areas of the body at diagnosis, the five-year survival rate is 29%.

Prevention

There is no clear way to prevent bone sarcoma; however, certain preexisting conditions or genetic types may have a higher likelihood of developing these cancers. Screening and **genetic testing** may inform individuals of their risk of developing these cancers.

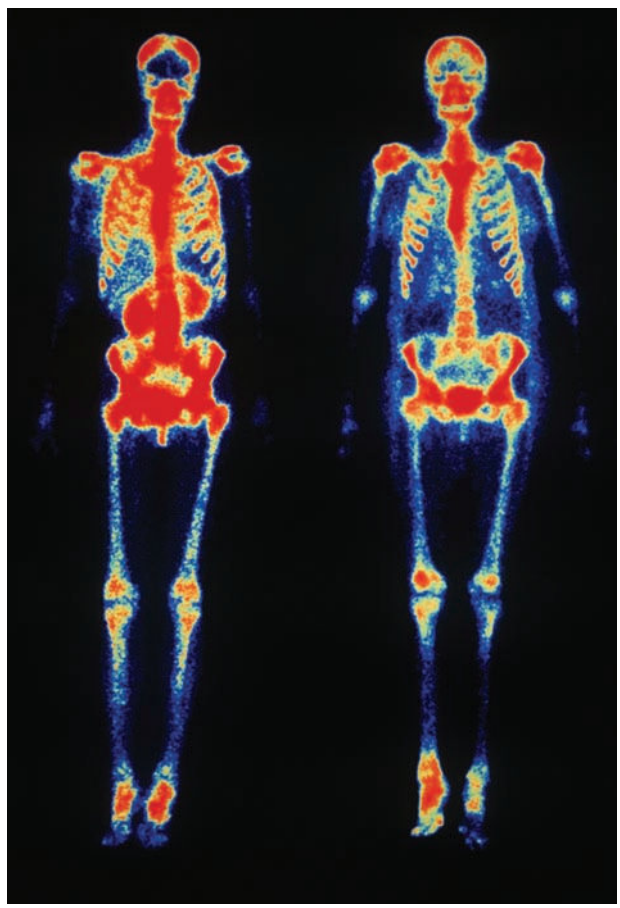
Bone scan

Definition

A bone scan is a diagnostic procedure used to evaluate abnormalities involving bones and joints. A radioactive substance is injected intravenously, and the image of its distribution in the skeletal system is analyzed to detect certain diseases or conditions.

Purpose

Bone scans are most frequently ordered to check whether a cancer that originated elsewhere has spread to the bones. Cancers that begin in the breasts, kidneys, lungs, prostate, thyroid, or urinary bladder are most likely to spread, or metastasize, to the bones. If metastases are found, periodic bone scans may be ordered to see if therapy is effective against a cancer.



Full body bone scan revealing cancer metastases. *(Scott Camazine & Sue Trainor/Science Source/Photo Researchers, Inc.)*

KEY TERMS

Osteoarthritis—A form of arthritis that occurs mainly in older people and involves the gradual degeneration of the cartilage of the joints.

Osteomalacia—A softening of bones caused by lack of vitamin D and/or calcium in the diet.

Osteoporosis—A condition found in older individuals in which bones decrease in density and become fragile and more likely to break. It can be caused by lack of vitamin D and/or calcium in the diet.

Radioisotope—A radioactive, or radiation-emitting form, of an element.

Radiologist—A medical doctor specially trained in radiology (x ray) interpretation and its use in the diagnosis of diseases and injuries.

Radionuclide—A substance that emits radiation as it disintegrates.

Some cancers arise in bone. These are called primary bone cancers. When an abnormality is found on an x ray of a bone, a bone scan may be helpful in deciding if it is a primary **bone cancer**, or a noncancerous (benign) condition.

Infection in the bone (**osteomyelitis**) can be detected or confirmed by a bone scan, often days or weeks before an x ray would reveal it. Bone scans are useful in diagnosing early arthritic changes, and monitoring both the progression of the disease and the effectiveness of treatment. Unexplained **pain** may be evaluated with a bone scan, because it can demonstrate **fractures** that are difficult to detect on x ray. Bone scans can be used to see if artificial joints have loosened or become infected. Suspected **child abuse** may be evaluated with a bone scan, due to its ability to show an overall pattern of repeated **trauma**. Abnormalities caused by altered circulation to the bone may be diagnosed with a bone scan.

Precautions

Women who are pregnant or breastfeeding should not have this test. A patient who is unable to remain still for an extended period of time may require **sedation** for a bone scan.

Description

This test is performed in a **radiology** facility, either in a hospital department or an outpatient x-ray center. The patient usually sits or lies down while a radioactive substance is injected through a vein in the arm. For a bone scan, the radionuclide used is specifically chosen to accumulate in the bone. The patient then waits from three to four hours for the substance to collect within the skeletal system. During this time, he or she will be instructed to drink several glasses of water. Patients are free to get up and move around as they desire during this waiting time, and should urinate frequently. Just before the scanning begins, patients should empty their bladder again. This ensures that a lot of radioactive material is not concentrated in the urinary bladder, which could obscure part of the pelvic bones.

During the scan, patients lie on their back on a table, but may be repositioned to the stomach or side during the study. It is important for the patient not to move, except when directed to by the technologist.

The radionuclide scanner, sometimes called a gamma camera, or scintillation camera, is positioned against the body part to be examined. Either the camera, the table, or both, may change position during the study. For a total body bone scan, the patient is scanned from head to foot, over a period of 30–60 minutes. Patients should experience no discomfort from this examination.

A special kind of bone scan, called a **single photon emission computed tomography** (SPECT) scan, may be added to study a particular part of the body in more detail. Suspected diseases of the hips, lower back, or jaw are often evaluated using this study. It usually takes an additional 30–45 minutes. The camera circles completely around the area in question or multiple cameras are used to create a cross-sectional image. This helps pinpoint the location of the abnormality being evaluated.

The bone scan might be done in phases. The procedure is the same, except the scanning takes place immediately after the radioactive substance is injected, then again at set intervals to image how the radioactive tracer pools and distributes in the body and bone. For example, a two-phase bone scan for osteomyelitis may involve a scan about five minutes after injection, then about three hours later.

Preparation

Some specialized blood studies should be drawn before this study is begun. Jewelry or metallic objects need to be removed. No other special physical preparation is required.

WWW.BOOKBAZ.IR

The patient should understand that there is no danger of radioactive exposure to themselves or others, as only small amounts of the radioisotope are used. The total dose of radiation absorbed is minimal, often less than the amount received from ordinary x rays. The radionuclide scanner does not emit any radiation at all, but detects and records it from the patient.

Aftercare

Fluids are encouraged after the scan to aid in the excretion of the radioisotope. It is almost completely eliminated from the body within 24 hours. However, since increased airport security methods resulting from the September 11, 2001, attacks, isolated cases of people who have had recent diagnostic nuclear medicine procedures setting off airport security systems have occurred. One state's Homeland Security Department has warned people having nuclear medicine procedures and flying soon afterward to bring adequate documentation of the procedure along to the airport.

Results

The normal appearance of the scan will vary according to the patient's age. In general, a uniform concentration of radionuclide uptake is present in all bones in a normal scan.

Abnormal results

A high concentration of radionuclide occurs in areas of increased bone activity. These regions appear brighter and may be referred to as "hot spots." They may indicate healing fractures, tumors, infections, or other processes that trigger new bone formation. Lower concentrations of radionuclide may be called "cold spots." Poor blood flow to an area of bone or bone destruction from a tumor may produce a cold spot.

The bone scan is a very sensitive test and can detect subtle conditions more readily than other studies. However, it is not a very specific examination, and often cannot distinguish exactly what disease process is causing an abnormality. Results need to be correlated with the patient's medical history and other radiologic and laboratory studies to make a definite diagnosis.

Bone tumor *see* **Sarcomas**

Bone x rays

Definition

Bone x rays are a diagnostic imaging test in which ionizing radiation passing through the bones enables an image to be produced on film. An x ray (radiograph) can produce an image of a bone from various and multiple angles. A physician may view an x-ray film to help diagnose **fractures** in patients and then consider treatment options based on the findings. An x ray may be taken of many bones in the body including the hand, foot, wrist, spine, rib cage, and ankle.

Purpose

Bone x rays are ordered to detect bone disease or injury, such as in the case of broken bones, tumors, and other problems. They can determine bone density, texture, erosion, and changes in bone relationships. Bone x rays also evaluate the joints for such diseases as arthritis. In addition, x rays may be taken to see if a joint has been dislocated, to guide a surgeon during an orthopedic surgical procedure such as a total joint replacement operation, to visualize **foreign objects**, or to check bone alignment before and after cast application or repair via screw and plate orthopedic procedures.

Description

X rays are the result of the collision between electrons and protons. German physicist Wilhelm Conrad Röntgen (1845–1923), discovered what he called X-radiation, in 1895. This form of radiation was noted to have properties allowing transparency and fluorescence that absorbed visible light and contrasting shadows. Experiments with this new form of radiation revealed the distinction between bone and soft tissues in the body, such as in the hand. Röntgen's first x ray was of his wife's hand, which showed bones, soft tissue, and metal from the ring she was wearing. His discovery of x rays heralded a significant and valuable diagnostic tool used in the field of medicine. Röntgen was awarded the Nobel Prize for Physics in 1901 for his discovery. He was the first recipient to be honored in this category. This Nobel Laureate was honored "in recognition of the extraordinary services he has rendered by the discovery of the remarkable rays subsequently named after him."

X rays are a common diagnostic test in which a form of energy called x-ray radiation penetrates the patient's body. In bone x rays, electrical current passes through an x-ray tube and produces a beam of ionizing radiation that passes through the bone(s) being examined. This produces a picture of the inside of the body on film. The doctor reads the developed x ray on a wall-mounted light box or on a computer monitor.

Digital x rays are a new type of exam in which conventional equipment is used to take the x-ray picture, but the image is produced via computer. In a digital x ray, the image is created on a reusable plate. After being read by a laser reader, the information is sent in digital form to a storage unit that is connected to a computer network. The radiologist reads the x ray from there. An electronic report can then be sent to the patient's doctor. Electronic reports can also be generated with non-digital x-ray exams.

X rays can detect problems with bones that result from injury or disease caused by malfunction in the patient's bone chemistry. Bone injuries, especially broken bones (fractures), are common and can be accurately diagnosed by evaluation of bone x rays. X rays are especially helpful in diagnosing simple and incomplete fractures, which cannot be detected during a **physical examination**. X rays can also be used to check for bone position and alignment in a fracture. Some bone diseases can be definitively diagnosed with bone x rays, while others require additional, more sophisticated imaging tests.

KEY TERMS

Arthritis—A disease of the joints that arises from wear and tear, age, and, less often, from inflammation.

Bone densitometry—A test to measure bone density.

Ionizing radiation—Energy from radio, ultraviolet, or x rays, that produces charged particles in the recipient matter.

Osteoporosis—A disease that occurs primarily in postmenopausal women in which the amount of bone is reduced or skeletal tissue wastes away.

Osteoporosis, a common bone disease, can be detected in bone x rays, but other tests, such as bone densitometry, may need to be ordered to determine the extent of the disease. In some cases, a **bone biopsy** (microscopic analysis of a small amount of tissue) is also done. For arthritis, a common ailment, x rays of the bone are occasionally used in conjunction with blood tests. In bone tumors, bone x rays can be helpful, but they may not be definitive when used alone.

Bone x rays are taken by a technologist or radiologist and interpreted by a radiologist. They are taken in a doctor's office, in a hospital, or in an outpatient clinic. Bone x rays generally take less than 10 minutes to complete. There is no **pain** or discomfort associated with the test, but some people find it difficult to remain still throughout the procedure.

During the test, the patient lies on a table. The technician taking the x ray checks the patient's position and places the x ray machine over the part of the body being scanned. After asking the patient to remain still, the technician steps out of the area and presses a button to take the picture.

Preparation

The patient is asked to remove clothing, jewelry, and any other metal objects from the part of the body being x rayed. If appropriate, a lead shield is placed over another part of the body to minimize exposure to the radiation that is being used.

Aftercare

The patient can immediately resume normal activities once the technician has checked that the x rays have processed well and that none need to be repeated. This takes just a few minutes.

WWW.BOOKBAZ.IR

Risks

The human body contains some natural radiation and is also exposed to radiation in the environment. There is a slight risk from exposure to radiation during bone x rays; however, the amount of radiation is small and the risk of harm is very low. If reproductive organs are to be exposed to large amounts of radiation, genetic alterations could occur in a developing fetus. Excessive or repeated doses of radiation can cause changes in other types of body tissue. No radiation remains in the body after the x ray.

Results

Normal bones show no fractures, **dislocations**, or other abnormalities.

Results that indicate the presence of bone injury or disease differ in appearance, according to the nature of the injury or disease. For example, fractures show up as clear breaks in the bones, while osteoporotic bone has the same shape as normal bone on an x-ray, but is less dense.

Borderline personality disorder

Definition

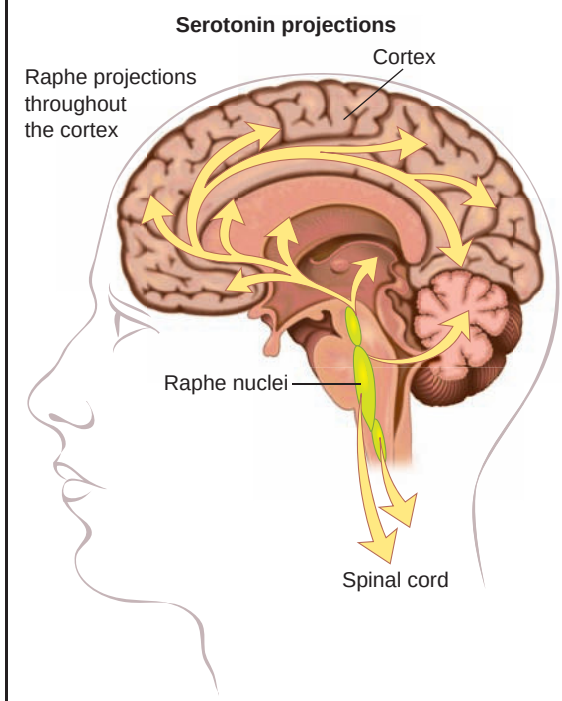
Borderline personality disorder (BPD) is a serious mental illness characterized by an inability to regulate emotional responses and moods, impacting self-image and interpersonal relationships. BPD can result in impulsive, self-harming, and suicidal behaviors; substance abuse; **eating disorders**; and the disruption of family life.

Demographics

BPD accounts for 30%–60% of all diagnosed **personality disorders**. According to the National Institutes of Mental Health, approximately 2% of Americans suffer from BPD. About 20% of all psychiatric hospitalizations are due to BPD. The disorder usually becomes evident in early adulthood, with a typical age of onset of 18 years. BPD is rarely initially diagnosed in people over age 40. Though as many as 80% of patients treated for BPD are female, this gender bias is less obvious in samples from community populations, suggesting that women may be more likely than men to seek treatment. BPD appears to be equally common among all races and ethnicities. Although the suicidal thinking and **suicide** attempts that are characteristic of BPD are less common in traditional societies, they are becoming increasingly common both in modern societies and in traditional societies that are undergoing rapid change.

Description

The term *borderline* in BPD is now considered a misnomer. It was originally used by the psychologist Adolf Stern in the 1930s to describe patients with neuroses that bordered on **psychosis**. Today the term more often refers to borderline states of consciousness that BPD patients may feel when they are experiencing dissociative symptoms—feelings of disconnection from



Borderline personality disorder

Diagnostic criteria for borderline personality disorder

Affective (mood-related) symptoms
1. Unstable mood caused by brief but intense episodes of depression, irritability, or anxiety
2. Chronic feelings of emptiness
3. Inappropriate and intense anger or difficulty controlling anger

Impulsive symptoms
4. Impulsive behavior in at least two areas (e.g., spending money, substance abuse, binge eating)
5. Recurrent suicidal behavior, gestures, or threats, or recurring acts of self-mutilation
6. Pattern of unstable and intense interpersonal relationships

Interpersonal symptoms
7. Extreme, persistently unstable perception of self
8. Frantic efforts to avoid abandonment

Cognitive symptoms
9. Stress-related paranoia and/or feeling disconnected from oneself

The Diagnostic and Statistical Manual of Mental Disorders states that the presence of five or more symptoms is necessary to diagnose BPD.

Diagnostic criteria for borderline personality disorder according to the *Diagnostic and Statistical Manual of Mental Disorders (DSM IV).* *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

oneself. People with BPD and other personality disorders often utilize coping strategies or defense mechanisms to deny responsibility for their emotions and behaviors.

BPD is a complex disorder with many manifestations. One major feature of BPD is a defense mechanism called "splitting," in which patients alternate between idealizing the significant people in their lives as flawless and devaluing them as unfair and uncaring. Their unrealistic expectations of others inevitably lead to disappointment and unstable interpersonal relationships. Another defense mechanism is referred to as "projective identification," in which patients attribute their own feelings to others and behave in ways that reinforce those attributes. When BPD patients' hostilities are reciprocated, they do not realize that it is due to their own hostility.

BPD results in a high degree of interpersonal conflict, estrangement of family and friends, and divorce. It is also linked to substance abuse, eating disorders, and a history of physical, sexual, or emotional abuse. Self-injury and suicide attempts are common among BPD patients.

Risk factors

Abuse or other childhood **trauma**, such as separation, neglect, or abandonment, is a major risk factor for BPD. According to the National Institute of Mental Health, studies have found that between 40% and 71% of patients diagnosed with BPD report having been sexually abused as children, most often by someone who was not their primary caregiver. However, most abused children do not develop BPD, and many BPD patients were not abused as children. Rather, abuse appears to act as a trigger in people who are genetically predisposed to BPD. Studies of twins suggest that at least some features of BPD, especially mood instability and impulsivity, are highly heritable.

Causes and symptoms

The biological basis of BPD is an area of active research. Recent studies suggest that BPD may involve differences in the functioning of the brain's endogenous opioid system, which helps regulate emotions. BPD may also involve disruptions in signaling pathways in the brain, involving the neurotransmitters serotonin, norepinephrine, and acetylcholine, which help regulate emotions such as **anxiety**, sadness,

WWW.BOOKBAZ.IR

irritability, and anger. Feelings of inadequacy and self-loathing arising from childhood abuse or neglect appear to contribute to the development of BPD. It has been theorized that the idealized demands that adults with BPD make on themselves and others are attempts to compensate for care and nurturing denied in childhood.

BPD was first defined as a disorder in the third edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-III*), published in 1980 and revised in subsequent editions. The revised fourth edition, *DSM-IV-TR,* requires that at least five symptoms be present for a diagnosis of BPD. However some clinicians suggest that a diagnosis should require symptoms from each of the three following dimensions or groupings:

- The affective dimension includes mood-related symptoms, such as brief—but intense—episodes of depression, irritability, anxiety, and, especially, inappropriate outbursts of sarcasm, anger, and/or physical violence. The level of mood instability can be a strong predictor of suicide attempts. Other affective symptoms include chronic feelings of emptiness.
- The impulsive dimension includes impulsive behaviors in at least two areas, such as spending money, sex, substance abuse, reckless driving, or binge eating. Impulsive symptoms also include recurrent suicidal threats, gestures, or behaviors, as well as recurring acts of self-mutilation, such as cutting or burning, which result from a combination of impulsivity and rapid and intense mood swings. These latter self-harming behaviors are not generally considered suicidal, but rather serve a personal purpose, such as providing relief from an extreme emotional state.
- The interpersonal dimension includes a pattern of intense but unstable interpersonal relationships, characterized by alternating idealization and devaluation or "love-hate." It also includes a persistently unstable self-image or sense of self and frantic efforts to avoid real or perceived abandonment.

There are also cognitive criteria for diagnosis of BPD that include stress-related, short-lived **paranoia** and/or severe dissociative symptoms—feeling disconnected from oneself, as if observing one's actions from the outside. Symptoms tend to be exacerbated by feelings of **isolation** and lack of social support. Patients may frantically try to avoid being alone. These symptoms can lead to frequent changes in relationships, jobs, long-term goals, or gender identity. Studies have found that as many as 40% of patients with BPD report having semi-psychotic thoughts and short delusional periods, and that the presence of psychotic symptoms can be a predictor of self-harming behaviors.

Although BPD symptoms can be similar to symptoms of the better known—but less common—schizophrenic and bipolar disorders, the intense episodes of anxiety, depression, or anger with BPD usually last only hours, rather than days or weeks. However, these episodes may be associated with impulsive aggression, substance abuse, or self-injury. Although patients with BPD may experience auditory **hallucinations**, they are aware that they are hallucinating, unlike patients with **schizophrenia**.

BPD is sometimes difficult to diagnose in adolescence, since symptoms such as impulsive and experimental behaviors, insecurity, and mood swings are common in teenagers. Some researchers have further suggested that BPD is not a defined pathological condition but rather overlapping symptoms of other personality disorders.

Diagnosis

Clinicians diagnose BPD on the basis of interviews with the patient and a complete personality assessment. With the patient's permission, family members and friends also may be interviewed. The clinician may require that symptoms that have been consistently present over time match at least five of the nine criteria in the *DSM-IV-TR*. The clinician should rule out chronic substance abuse and/or medical conditions, especially central nervous system disorders, which can cause similar symptoms. The clinician will attempt to identify problems that often occur in conjunction with BPD, including **mood disorders** such as depression or anxiety, **post-traumatic stress disorder** (PTSD), eating disorders, or **attention deficit hyperactivity disorder (ADHD)**.

Treatment

Traditional

Individuals with BPD seek psychiatric help and hospitalization at a much higher rate than people with other personality disorders, perhaps because of their fear of abandonment and their search for idealized interpersonal relationships. **Psychotherapy** is the treatment of choice for BPD, and patients often require long-term services. Dialectical behavior therapy (DBT), a type of **cognitive-behavioral therapy** (CBT), has emerged as an effective therapy for individuals with suicidal tendencies. This treatment focuses on decreasing self-harming behaviors and building self-confidence and coping skills through a

KEY TERMS

Attention deficit hyperactivity disorder (ADHD)—Conditions characterized by age-inappropriate attention span, hyperactivity, and impulsive behavior.

Bipolar disorder—A recurrent mood disorder, also known as manic-depressive disorder, in which patients have extreme mood swings from depression to mania or a mixture of both.

Cognitive—Conscious intellectual activity, including thinking, imagining, reasoning, remembering, and learning.

Cognitive-behavioral therapy (CBT)—A type of psychotherapy in which people learn to recognize and change negative and self-defeating patterns of thinking and behavior.

Depression—A mental condition in which a person feels extremely sad and loses interest in life. A depressed person may have problems with appetite, sleep, concentration, and daily functioning. Severe depression can lead to suicide attempts.

Dialectical behavior therapy (DBT)—A type of cognitive-behavioral therapy designed specifically to treat borderline personality disorder.

Dissociative—Descriptive of a person who dissociates or detaches from reality, sometimes as a coping mechanism.

Eating disorder—A condition characterized by an abnormal attitude toward food, altered appetite control, and unhealthy eating habits.

Neurotransmitters—Chemicals that transmit nerve impulses from one nerve cell to another.

Opioids—A group of endogenous polypeptides in the brain that bind to opiate receptors.

Post-traumatic stress disorder (PTSD)—A psychological response to a highly stressful event; typically characterized by depression, anxiety, flashbacks, nightmares, and avoidance of reminders of the traumatic experience.

Psychodynamic—Mental, emotional, or motivational forces or processes that affect mental state and behavior, especially unconscious processes that develop in early childhood.

Psychosis—A serious mental disorder, such as schizophrenia, characterized by loss of contact with reality.

Schizophrenia—A psychotic disorder characterized by loss of contact with one's environment, deterioration of everyday functioning, and personality disintegration.

Serotonin—A neurotransmitter located primarily in the brain, blood serum, and stomach membrane.

combination of social skills training, mood awareness, meditative exercises, and education about the disorder. **Group therapy** is a component of DBT and is an option for some BPD patients, although patients may feel threatened by the idea of "sharing" their therapist with others.

The nature of BPD makes it a challenging disorder to treat effectively. The therapist-patient relationship is subject to the same inappropriate and unrealistic demands that individuals with BPD place on all of their significant personal relationships. Individuals with BPD are often chronic treatment seekers, who become easily frustrated when they feel that the therapist is not providing adequate attention or empathy. Symptomatic anger, impulsivity, and self-destructive behaviors can further impede the therapist-patient relationship. In addition, some BPD patients may resent any progress in therapy because of their fear of abandonment or of ending the therapist relationship. Addressing the high incidence of suicidal thoughts and tendencies in BPD patients is also a major therapeutic challenge.

Drugs

Medications are often used in conjunction with psychotherapy to treat symptoms of BPD. Antidepressants, especially those that enhance the activity of the neurotransmitter serotonin, can improve emotional symptoms. Mood-stabilizing drugs that enhance the activity of gamma-aminobutyric acid (GABA), the primary inhibitory neurotransmitter in the brain, may help with BPD mood swings. In severe cases, **antipsychotic drugs** may be prescribed. Some patients take several different medications, each designed to address a different manifestation of BPD. However, drugs are rarely effective without individual and group or **family therapy**.

Alternatives

Several new psychotherapies have been developed for treating BPD; however, little research on their efficacy has been conducted. Schema therapy combines CBT with techniques from psychodynamic therapies to examine repetitive life patterns or schemas. Mentalization therapy is geared toward helping patients perceive the minds of

WWW.BOOKBAZ.IR

others as distinct from their own, thereby enabling them to reassess their perceptions of reality. Transference-focused psychotherapy (TFP) is a psychodynamic treatment that attempts to correct patients' perceptions of their therapist and other important people in their lives.

Home remedies

BPD is a serious disorder that requires extensive mental health services and possibly medications. However, because symptoms of the illness are usually focused on interpersonal relationships, family members may need support and therapy as well.

Prognosis

Treatments for BPD have improved in the early 2000s, and many patients are eventually able to lead productive lives. Symptoms of the disorder usually peak in young adulthood and frequently stabilize after age 30, with symptoms improving in later adulthood, especially by about age 40. However, individuals with BPD are at very high risk for suicide attempts. Although estimates vary widely, some studies have found that as many as 80% of those with BPD attempt suicide at least once, and as many as 10% complete suicide. Although suicidal behavior usually peaks when patients are in their mid-20s, most completed suicides occur among patients over 30 and most often involve those who have experienced no improvement after numerous attempts at treatment. BPD patients with a diagnosed depressive disorder have a much higher risk of suicide and require swift diagnosis and appropriate intervention. Adults with BPD also are at higher risk for becoming victims of violence, including rape. This may be due to poor judgment and impulsive behaviors that result in patients choosing inappropriate partners and dangerous lifestyles and environments.

Prevention

BPD is thought to result from a complex of causes, and there is no known prevention, other than ensuring a safe and nurturing childhood environment for those at risk for the disorder. Prompt, appropriate treatment for BPD is crucial for preventing the worsening of symptoms and suicidal behaviors.

Botulinum toxin injections

Definition

Botulinum is a bacterium (*Clostridium botulinum*) that produces seven different toxins that can cause **botulism** and is also medically used to block muscle contractions. Botulinum toxin is commonly referred to as Botox.

Description

The number of potential applications for botulinum toxin extends to every muscle group. The first therapeutic use of Botox was in the treatment of **strabismus** (eyes that are unable to direct toward the same object), and subsequently it was used to treat a variety of involuntary muscle contractions or disorders. Frequently, its cosmetic use is to smooth facial lines.

The effect of toxin type A lasts approximately three months and is the therapeutic agent of choice for many conditions.

Purpose

Botox injection is used in conditions of excessive and inappropriate muscle contraction, spasticity (persistent states of muscle contraction), sphincter contraction, eye-movement disorders, tics and **tremors**, and cosmetically to treat facial lines and wrinkles. Botox is used to treat excessive underarm perspiration. It has also been approved for spastic cervical torticolis and upper limb spasticity, symptoms that can be experienced by some people who have suffered a **stroke** or brain injury.

Botox has also been used in the treatment of chronic muscle tension and migraine headaches. The relief is likely due to the decrease in localized **muscle spasms**, as Botox does not appear to effect sensory nerves. Botox may be recommended to help improve movement in children with **cerebral palsy**, but this off-label use was not approved by the FDA as of 2014.

Preparation

The dosage of Botox must be monitored and adjusted, with multiple injections showing a lower incidence of complications than administration of one larger dose.

Precautions

Botulinum toxin is produced from the bacterium that causes **food poisoning** in humans. High doses of the toxin can be fatal; however, doses administered therapeutically are so small that harmful effects are uncommon.

Risks

Between 1970 and the early 2000s the therapeutic use in humans of botulinum toxin proved to be safe. However, different patients may experience different effects from the same dose. Patients new to the treatment may experience exaggerated effects from subsequent treatments, and neighboring muscles may become activated as a result of subsequent treatments. Patients should ask about their provider's experience with injecting Botox before receiving the procedure.

Additional side effects may include excessive muscle weakness at the injection site or adjacent muscles. These effects typically resolve quickly. Occasionally, patients report flu-like symptoms.

WWW.BOOKBAZ.IR

KEY TERMS

Antibody—A protein developed in response to the presence of a foreign substance.

Antigen—A foreign substance that causes an antibody response in the body.

Some patients may be resistant to the toxin. The presence of circulating antibodies to the toxin is presumed to be the primary reason for resistance to Botox injections. Patients who have little reaction to Botox A may benefit from injections using one of the other six serotypes. Using the smallest effective dose limits the likelihood of immunoresistance.

Results

The anticipated outcome of Botox injections is relaxation of the target muscle tissue. The effects of botulinum toxin are typically isolated to local areas and do not result in prolonged **paralysis** or tissue destruction.

Most side effects, such as weakness in the injected muscle or overall muscle soreness, go away quickly. Some patients received too much of the substance for cosmetic purposes and are unhappy with the results. Physicians and patients should discuss the procedure and the amount of Botox to be used. Many clinicians believe that it is best to err on the side of low dosage with a return trip for more, rather than too high a dosage that might result in unwanted cosmetic effects.

Botulism

Definition

Botulism is caused by botulinum toxin, a natural poison produced by certain bacteria in the *Clostridium* genus. Exposure to the botulinum toxin occurs mostly from eating contaminated food, or in infants, from certain clostridia growing in the intestine. Botulinum toxin blocks the motor nerves' ability to release acetylcholine, the neurotransmitter that relays nerve signals to muscles, and flaccid paralysisoccurs. As botulism progresses, the muscles that control the airway and breathing fail.

Description

Botulism occurs rarely, but it causes concern because of its high fatality rate. Clinical descriptions of botulism possibly reach as far back in history as ancient Rome and Greece. However, the relationship between contaminated food and botulism was not defined until the late 1700s. In 1793 the German physician Justinius Kerner deduced that a substance in spoiled sausages, which he called *wurstgift* (German for sausage poison), caused botulism. The toxin's origin and identity remained elusive until Emile von Ermengem, a Belgian professor, isolated *Clostridium botulinum* in 1895 and identified it as the poison source.

Three types of botulism have been identified: food-borne, wound, and infant botulism. The main difference between types hinges on the route of exposure to the toxin. In the United States, there are approximately 110 cases of botulism reported annually. Food-borne botulism accounts for 25% of all botulism cases and usually can be traced to eating contaminated home-preserved food. Infant botulism accounts for 72% of all cases, but the recovery rate is good (about 98%) with proper treatment. From 1990 to 2000, 263 cases of food-borne cases were reported in the United States, most of them in Alaska. Though most were related to home canning, two restaurant-associated outbreaks affected 25 people.

Though domestic **food poisoning** is a problem worldwide, there has been a growing concern regarding the use of botulism toxin in biological warfare and terrorist acts. The Iraqi government admitted in 1995 that it had loaded 11,200 liters of botulinum toxin into SCUD missiles during the Gulf War. Luckily, these special missiles were never used. There are 17 countries known to be developing biological weapons, including the culture of botulism toxins.

KEY TERMS

Acetylcholine—A chemical released by nerve cells to signal other cells.

Antitoxin—A substance that inactivates a poison (e.g., toxin) and protects the body from being injured by it.

Computized tomography (CT scan)—A test that may involve injection of a radioactive contrast into the body. Computers are used to scan for radiation and create cross-sectional images of internal organs.

Electromyograpy test—A medical test that determines a muscle's response to electrical stimuli. The test results allow medical personnel to assess how nerves to the muscle are functioning.

Flaccid paralysis—Paralysis characterized by limp, unresponsive muscles.

Lumbar puncture—A procedure in which a small amount of cerebrospinal fluid is removed from the lower spine. Examination of this fluid helps diagnose certain illnesses.

Magnetic resonance imaging (MRI)—A test that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Neurotransmitter—A chemical found in nerves that relays nerve signals to other cells. Acetylcholine is a neurotransmitter.

Sepsis—The presence of infection-causing organisms or associated toxins in the blood or within body tissues.

Spores—A state of "suspended animation" that some bacteria can adopt when conditions are not ideal for growth. Spores are analogous to plant seeds and can germinate as growing bacteria when conditions are right.

Toxin—A poisonous substance produced by a microorganism, plant, or animal.

Tracheostomy—The procedure used to open a hole in the neck to the trachea, or windpipe. It is sometimes used in conjunction with a respirator.

Causes and symptoms

Toxin produced by the bacterium *Clostridium botulinum* is the main culprit in botulism. Other members of the *clostridium* genus can produce botulinum toxin, namely *C. argentinense*, *C. butyricum*, and *C. baratii*, but they are minor sources. To grow, these bacteria require a low-acid, oxygen-free environment that is warm (40–120°F or 4.4–48.8°C) and moist. Lacking these conditions, the bacteria transform themselves into spores that, like plant seeds, can remain dormant for years. Clostridia and their spores exist all over the world, especially in soil and aquatic sediments. They do not threaten human or animal health until the spores encounter an environment that favors growth. The spores then germinate, and the growing bacteria produce the deadly botulism toxin.

Scientists have discovered that clostridia can produce at least seven types of botulism toxin, identified as A, B, C, D, E, F, and G. Humans are usually affected by A, B, E, and very rarely F. Domesticated animals such as dogs, cattle, and mink are affected by botulism C toxin, which also affects birds and has caused massive die-offs in domestic bird flocks and wild waterfowl. Botulism D toxin can cause illness in cattle, and horses succumb to botulism A, B, and C toxin. There have been no confirmed human or animal botulism cases linked to the G toxin.

In humans, botulinum toxin latches onto specific proteins in nerve endings and irreversibly destroys them. These proteins control the release of acetylcholine, a neurotransmitter that stimulates muscle cells. With acetylcholine release blocked, nerves are not able to stimulate muscles. Ironically, botulinum toxin has found a beneficial niche in the world of medicine due to this action. Certain medical disorders are characterized by involuntary and uncontrollable muscle contractions. Medical researchers have discovered that injecting a strictly controlled dose of botulinum toxin into affected muscles inhibits excessive muscle contractions. The muscle is partially paralyzed and normal movement is retained. This is commonly referred to as Botox injection.

The three types of human botulism have the following symptoms:

- Food-borne. Food that has been improperly preserved or stored can harbor botulinum toxin–producing clostridia. Botulism symptoms typically appear within 18–36 hours of eating contaminated food, with extremes of four hours to eight days.

WWW.BOOKBAZ.IR

Initial symptoms include blurred or double vision and difficulty swallowing and speaking. Possible gastrointestinal problems include constipation, nausea, and vomiting. As botulism progresses, the victim experiences weakness or paralysis, starting with the head muscles and progressing down the body. Breathing becomes increasingly difficult. Without medical care, respiratory failure and death are very likely.

- Infant. Infant botulism was first described in 1976. Unlike adults, infants younger than 12 months are vulnerable to *C. botulinum* colonizing the intestine. Infants ingest spores in honey or simply by swallowing spore-containing dust. The spores germinate in the large intestine and, as the bacteria grow, they produce botulinum toxin that is absorbed into the infant's body. The first symptoms include constipation, lethargy, and poor feeding. As infant botulism progresses, sucking and swallowing (thus eating) become difficult. A nursing mother will often notice breast engorgement as the first sign of her infant's illness. The baby suffers overall weakness and cannot control head movements. Because of the flaccid paralysis of the muscles, the baby appears "floppy." Breathing is impaired, and death from respiratory failure is a very real danger.
- Wound. Confirmed cases of wound botulism have been linked to trauma such as severe crush injuries to the extremities, surgery, and illegal drug use. Wound botulism occurs when clostridia colonize an infected wound and produce botulinum toxin. The symptoms usually appear four to 18 days after an injury occurs and are similar to food-borne botulism, although gastrointestinal symptoms may be absent.

Diagnosis

Diagnosis of botulism can be tricky because symptoms mimic those presented by other diseases. Botulism may be confused with **Guillain-Barre syndrome**, **myasthenia gravis**, drug reactions, **stroke**, or nervous system infection, intoxications (e.g. carbon monoxide or atropine), or shellfish **poisoning**. **Sepsis** is the most common initial diagnosis for infant botulism. **Failure to thrive** may also be suspected. Some reports have linked infant botulism to 5–15% of **sudden infant death syndrome** (SIDS, crib death) cases. Laboratory tests are used for definitive diagnosis, but if botulism seems likely, treatment starts immediately.

While waiting for laboratory results, doctors ask about recently consumed food and work to dismiss other disease possibilities. A **physical examination** is done with an emphasis on the nervous system. As part of this examination, CT scans, MRIs, electromyographic tests, or lumbar punctures may be ordered. Laboratory tests involve testing a suspected food and/or the patient's serum, feces, or other specimens for traces of botulinum toxin or clostridia.

Treatment

Drugs

Adults with botulism are treated with an antitoxin derived from horse serum that is distributed by the Centers for Disease Control and Prevention. The antitoxin (effective against toxin types A, B, and E) inactivates only the botulinum toxin that is unattached to nerve endings. Early injection of antitoxin (usually within 24 hours of onset of symptoms) can preserve nerve endings, prevent progression of the disease, and reduce mortality.

Infants, however, cannot receive the antitoxin used for adults. For them, human botulism immune globulin (BIG) is available in the United States through the Infant Botulism Treatment and Prevention Program in Berkeley, California. BIG neutralizes toxin types A, B, C, D, and E before they can bind to nerves. This antitoxin can provide protection against A and B toxins for approximately four months. Though many infants recover with supportive care, BIG cuts hospital stay in half, and therefore reduces hospital costs by 50% as well.

Aside from antitoxin, no drugs are used to treat botulism. **Antibiotics** are not effective for preventing or treating botulism. In fact, antibiotic use is discouraged for infants because dying bacteria could potentially release more toxin into a baby's system. Antibiotics can be used, however, to treat secondary respiratory tract and other infections.

Respiratory support

Treatment for infants usually involves intensive respiratory support and tube feeding for weeks or even months. Once an infant can breathe unaided, **physical therapy** is initiated to help the child relearn how to suck and swallow. A respirator is often required to help adult patients breathe, and a tracheostomy may also be necessary.

Surgery

Surgery may be necessary to clean an infected wound and remove the source of the bacteria that is

producing the toxin. Antimicrobial therapy may be necessary.

Gastric lavage

When botulism is caused by food, it often is necessary to flush the gastrointestinal tract (gastric lavage). Often cathartic agents or **enemas** are used. It is important to avoid products that contain magnesium, since magnesium enhances the effect of the toxin.

Prognosis

With medical intervention, botulism victims can recover completely, though slowly. It takes weeks to months to recover from botulism, and severe cases can take years before a total recovery is attained. Recovery depends on the nerve endings building new proteins to replace those destroyed by botulinum toxin.

Prevention

Vaccines against botulism do not exist to prevent infant botulism or other forms of the disease. However, scientists announced in 2004 that they had successfully vaccinated mice and ducks against type C and D, which may help lead to vaccines for humans. Food safety is the surest prevention for botulism. Botulinum toxin cannot be seen, smelled, or tasted, so the wisest course is to discard any food that seems spoiled *without tasting it*. Home canners must be diligent about using sterile equipment and following U.S. Department of Agriculture canning guidelines. If any part of a canned food container is rusty or bulging, the food should not be eaten. Infant botulism is difficult to prevent, because controlling what goes into an infant's mouth is often beyond control, especially in regard to spores in the air. One concrete preventive is to never feed honey to infants younger than 12 months since it is one known source of botulism spores. As infants begin eating solid foods, the same food precautions should be followed as for adults.

Bowel preparation

Definition

A bowel preparation (bowel prep) involves dietary changes and the use of cathartics, **laxatives**, and/or **enemas** to clean out the colon prior to tests or procedures involving the abdomen and gastrointestinal tract. It may also include the administration of **antibiotics** to lessen the chance of infection during surgery.

Purpose

Completing a bowel prep is important prior to a radiological examination, because stool in the intestine may interfere with viewing other structures or organs within the abdomen. Prior to abdominal surgery, a careful bowel prep is crucial, since the risk of severe, life-threatening infection is increased if stool remains in the colon. Because stool contains a high bacteria count, even a microscopic nick of the intestine during the course of surgery could result in contamination of the surgical field and the development of a severe infection.

Description

Although a number of different regimens can be followed, there is one basic methodology. Patients who are going to undergo a diagnostic test (such as **barium enema** or **endoscopy**) or abdominal surgery are asked to stop eating solid foods some hours prior to the procedure. They may be allowed to continue with a full liquid or clear liquid diet, depending on the procedure. At some point just prior to the surgery, however, they must not to take anything at all by mouth.

During the 12 or so hours prior to the test or procedure, a series of preparations (in pill or liquid form) are used in order to make sure that all stool is evacuated from the intestine. Enemas may also be used to make sure that the bowel is completely cleared of stool. Further protection from infection may involve the administration of either oral antibiotics over the 12 hours prior to surgery, or intravenous antibiotics in the several hours just prior to surgery.

WWW.BOOKBAZ.IR

KEY TERMS

Cathartic—An agent that stimulates defecation.

Enema—A procedure in which a liquid is injected through the anus and into the lower intestine to stimulate defecation.

Laxative—An agent that stimulates defecation.

Aftercare

Some people, especially those who are already in a debilitated state, may become weak or faint during the course of a bowel preparation. People at risk for this outcome should have someone stay with them as they perform the bowel prep, or they should talk to their healthcare providers about having the bowel prep done at a hospital.

Risks

Most healthy patients can follow a bowel prep regimen in their own home. However, some patients may require hospitalization if they are very weak or ill with a condition (such as **kidney disease** or **congestive heart failure**) that requires close monitoring of their hydration and electrolyte status during the bowel prep.

Results

Normal results occur when the bowel is completely cleared of stool prior to a procedure or operation.

Bowel resection

Definition

Bowel resection is a surgical procedure in which a diseased part of the large intestine is removed. The procedure is also known as colectomy, colon removal, colon resection, or resection of part of the large intestine.

Purpose

The large bowel, also called the large intestine, is a part of the digestive system. It runs from the small bowel (small intestine) to the rectum, which receives waste material from the small bowel. The large bowel's major function is to store waste and to absorb water from waste material. It consists of the following sections, any of which may become diseased:

- Colon. The colon averages some 60 in. (150 cm) in length. It is divided into four segments: the ascending colon, transverse colon, descending colon, and sigmoid colon. There are two bends (flexures) in the colon. The hepatic flexure is where the ascending colon joins the transverse colon. The splenic flexure is where the transverse colon merges into the descending colon.
- Cecum. This is the first portion of the large bowel that is joined to the small bowel. The appendix lies at the lowest portion of the cecum.
- Ascending colon. This segment is about 8 in. (20 cm) in length, and it extends upward from the cecum to the hepatic flexure near the liver.
- Transverse colon. This segment is usually more than 18 in. (46 cm) in length and extends across the upper abdomen to the splenic flexure.
- Descending colon. This segment is usually less than 12 in. (30 cm) long and extends from the splenic flexure downwards to the start of the pelvis.
- Sigmoid colon. An S-shaped segment that measures about 18 in. (46 cm); it extends from the descending colon to the rectum.

The wall of the colon is composed of four layers:

- Mucosa. This single layer of cell lining is flat and regenerates itself every three to eight days. Small glands lie beneath the surface.
- Submucosa. The area between the mucosa and circular muscle layer that is separated from the mucosa by a thin layer of muscle, the muscularis mucosa.
- Muscularis propria. The inner circular and outer longitudinal muscle layers.

- Serosa. The thick outer layer that covers the bowel and is single celled. It is similar to the peritoneum, the layer of cells that lines the abdomen.

The large intestine is also responsible for bacterial production and absorption of **vitamins**. Resection of a portion of the large intestine (or of the entire organ) may become necessary when it becomes diseased. The exact reasons for large bowel esection in any given patient may be complex and are always carefully evaluated by the treating physician or team. The procedure is usually performed to treat the following disorders or diseases of the large intestine:

- Cancer. Colon cancer is the second most common type of cancer diagnosed in the United States. Colon and rectum cancers, which are usually referred to as colorectal cancer, develop on the lining of the large intestine. Bowel resection may be indicated to remove the cancer.
- Diverticulitis. This condition is characterized by the inflammation of a diverticulum, especially of diverticula occurring in the colon, which may undergo perforation with abscess formation. The condition may be relieved by resecting the affected bowel section.
- Intestinal obstruction. This condition involves a partial or complete blockage of the bowel that results in the failure of the intestinal contents to pass through. It is usually treated by decompressing the intestine with suction using a nasogastric tube inserted into the stomach or intestine. In cases where decompression does not relieve the symptoms, or if tissue death is suspected, bowel resection may be considered.
- Ulcerative colitis. This condition is characterized by chronic inflammation of the large intestine and rectum resulting in bloody diarrhea. Surgery may be indicated when medical therapy does not improve the condition. Removal of the colon is curative and also removes the risk of colon cancer. About 25%–40% of ulcerative colitis patients must eventually have their colons removed because of massive bleeding, severe illness, rupture of the colon, or risk of cancer.
- Traumatic injuries. Accidents may result in bowel injuries that require resection.
- Pre-cancerous polyps. A colorectal polyp is a growth that projects from the lining of the colon. Polyps of the colon are usually benign and produce no symptoms, but they may cause rectal bleeding and develop into malignancies over time. When polyps have a high chance of becoming cancerous, bowel resection may be indicated.
- Familial adenomatous polyposis (FAP). This is a hereditary condition caused by a faulty gene. Most people discover that they have it at a young age. People with FAP grow many polyps in the bowel. These are mostly benign, but because there are so many, it is really only a question of time before one becomes cancerous. Since people with FAP have a very high risk of developing bowel cancer, bowel resection is thus often indicated.
- Hirschsprung's disease (HD). This condition usually occurs in children. It causes constipation, meaning that bowel movements are difficult. Some children with HD cannot have bowel movements at all; the stool creates a blockage in the intestine. If HD is not treated, stool can fill up the large intestine and cause serious problems such as infection, bursting of the colon, and even death.

Description

Bowel resection surgery is performed by a colorectal surgeon, who is a medical doctor fully trained in **general surgery** and certified by the American Board of Surgery (ABS) as well as by the American Society of Colon and Rectal Surgeons (ASCRS). The surgeon must pass the American Board of Surgery Certifying Examination and complete an approved colorectal training program. The surgeon is then eligible to take the qualifying examination in colorectal surgery after completing training. There is also a certifying examination that is taken after passing the qualifying examination. The surgeon is required to recertify in surgery in order to recertify in colon and rectal surgery (every 10 years).

Bowel resection surgery is a major operation performed in a hospital setting. The cost of the surgery varies significantly between surgeons, medical facilities, and regions of the country. Patients who are sicker or need more extensive surgery will require more intensive and expensive treatment.

Bowel resection can be performed using an open surgical approach (colectomy) or laparoscopically.

Colectomy

Following adequate **bowel preparation**, the patient is placed under general **anesthesia**, which ensures that the patient is deep asleep and **pain** free during surgery. Because the effects of gravity to displace tissues and organs away from the site of operation are important, patients are carefully positioned, padded, and strapped to the operating table to prevent movement as the patient is tilted to an extreme degree. The surgeon starts the procedure by making a lower midline incision in the abdomen or, alternatively, it may be preferable to perform a lateral lower transverse incision instead. The operation proceeds with the

WWW.BOOKBAZ.IR

KEY TERMS

Anesthesia—A combination of drugs administered by a variety of techniques by trained professionals that provide sedation, amnesia, analgesia, and immobility adequate for the accomplishment of the surgical procedure with minimal discomfort and without injury to the patient.

Anus—The terminal orifice of the bowel.

Cancer—The uncontrolled growth of abnormal cells that have mutated from normal tissues.

Colectomy—The surgical removal of the colon or part of the colon.

Colon—Also called the large intestine, the organ that is responsible for forming, storing and expelling waste matter.

Colostomy—The surgical construction of an artificial anus between the colon and the surface of the abdomen.

Diverticulum—A small, pouch-like structure that sometimes forms in the walls of the intestines and can trap particles of food and become inflamed and painful.

Enema—A procedure in which a liquid is injected into the rectum.

Mesentery—The membranes, or one of the membranes (consisting of a fold of the peritoneum and enclosed tissues), that connect the intestines and their appendages with the dorsal wall of the abdominal cavity.

Ostomy—An operation to create an opening from an area inside the body to the outside.

Polyp—Growth, usually benign, protruding from a mucous membrane such as that lining the walls of the intestines.

Resection—Removal of a portion, or all, of an organ or other structure.

removal of the diseased portion of the large intestine, and then the two healthy ends are sutured or stapled back together before closing the incision. The amount of bowel removed can vary considerably, depending on the reasons for the operation. When possible, the procedure is performed to maintain the continuity of the bowel so as to preserve normal passage of stool.

If the bowel has to be relieved of its normal digestive work while it heals, a temporary opening of the colon onto the skin of abdominal wall, called a **colostomy**, may be created. In this procedure, the end of the colon is passed through the abdominal wall and the edges are sutured to the skin. A removable bag is attached around the colostomy site so that stool may pass into the bag, which can be emptied several times during the day. Most colostomies are temporary and can be closed with another operation at a later date. However, if a large portion of the intestine is removed, or if the distal end of the colon is too diseased to reconnect to the proximal intestine, the colostomy is permanent.

Laparoscopic bowel resection

The benefits of laparoscopic bowel resection when compared to open colectomies include reduced postoperative pain, shorter hospitalization periods, and a faster return to normal activities. The procedure is also minimally invasive. When performing a laparoscopic procedure, the surgeon makes three or four small incisions in the abdomen or in the umbilicus (belly button). He or she inserts specialized surgical instruments, including a thin, telescope-like instrument called a laparoscope, into an incision. The abdomen is then filled with gas, usually carbon dioxide, to help the surgeon view the abdominal cavity. A camera is inserted through one of the tubes and displays images on a monitor located near the operating table to guide the surgeon during the procedure. Once an adequate view of the operative field is obtained, the actual dissection of the colon can start. Following the procedure, the small incisions are closed with sutures or surgical tape.

All colon surgery involves only three maneuvers that may vary in complexity depending on the region of the bowel and the nature of the disease. The three maneuvers are retraction of the colon, division of the attachments to the colon, and dissection of the mesentery.

In a typical procedure, after retracting the colon, the surgeon proceeds to divide the attachments to the liver and the small bowel. Once the mesenteric vessels have been dissected and divided, the colon is divided with special stapling devices that close off the bowel and cut between the staple lines. Alternatively, a laparoscopically assisted procedure may be selected, in which a small abdominal wall incision is made at this point to bring the bowel outside of the abdomen, allowing open bowel resection and reconnection using standard instruments. This technique is popular with many surgeons because an incision must be made to remove the bowel specimen from the abdomen, which allows the most time-consuming and risky parts of the procedure

(from an infection point of view) to be done outside the body with better control of the colon.

Preparation

Key elements of the **physical examination** before surgery focus on a thorough examination of the abdomen, groin, and rectum. Other common diagnostic tools used to evaluate medical conditions that may require bowel resection include imaging tests such as gastrointestinal barium series, **angiography**, computed tomography (CT), **magnetic resonance imaging** (MRI), and **endoscopy**.

As with any surgery, the patient is required to sign a consent form. Details of the procedure are discussed with the patient, including goals, technique, and risks. Blood and urine tests, along with various imaging tests and an electrocardiogram (EKG), may be ordered. To prepare for the procedure, the patient is asked to completely clean out the bowel. This is a crucial step if the bowel is to be opened safely within the peritoneal cavity, or even manipulated safely through small incisions. To empty and cleanse the bowel, the patient is usually placed on a low-residue diet for several days prior to surgery. A liquid diet may be ordered for at least the day before surgery, with nothing taken by mouth after midnight. A series of **enemas** and/or oral preparations (Golytely or Colyte) may be ordered to empty the bowel of stool. Preoperative bowel preparation involving mechanical cleansing and administration of intravenous **antibiotics** immediately before surgery is the standard practice.

The patient may also be given a prescription for oral antibiotics (neomycin, erythromycin, or kanamycin sulfate) the day before surgery to decrease bacteria in the intestine and to help prevent postoperative infection. A **nasogastric tube** is inserted through the nose into the stomach during surgery and may be left in place for 24–48 hours after surgery. This removes the gastric secretions and prevents **nausea and vomiting**. A urinary catheter (a thin tube) may be inserted to keep the bladder empty during surgery, giving more space in the surgical field and decreasing chances of accidental injury.

Aftercare

Postoperative care for the patient involves monitoring blood pressure, pulse, respiration, and temperature. Breathing tends to be shallow because of the effect of anesthesia and the patient's reluctance to breathe deeply and experience pain that is caused by the abdominal incision. The patient is instructed how to support the operative site during deep breathing and coughing, and is given pain medication as necessary. Fluid intake and output is measured, and the operative site is observed for color and amount of wound drainage. The nasogastric tube will remain in place and attached to low intermittent suction until bowel activity resumes. Fluids and electrolytes are infused intravenously until the patient's diet can gradually be resumed, beginning with liquids and advancing to a regular diet as tolerated. The patient is generally out of bed approximately eight to 24 hours after surgery. Most patients will stay in the hospital for five to seven days, although laparoscopic surgery can reduce that stay to two to three days. Postoperative weight loss follows almost all bowel resections. Weight and strength are slowly regained over the next few months. Complete recovery from surgery may take two months. Laparoscopic surgery can reduce this time to one to two weeks.

The treating physician should be informed of any of the following problems after surgery:

- increased pain, swelling, redness, drainage, or bleeding in the surgical area
- headache, muscle aches, dizziness, or fever
- increased abdominal pain or swelling; constipation; nausea or vomiting; rectal bleeding; or black, tarry stools

Risks

Potential complications of bowel resection surgery include:

- excessive bleeding
- surgical wound infection
- incisional hernia (an organ projecting through the surrounding muscle wall; it occurs through the surgical scar)
- thrombophlebitis (inflammation and blood clot to veins in the legs)
- narrowing of the opening (stoma)
- pneumonia
- pulmonary embolism (blood clot or air bubble in the lung blood supply)
- reaction to medication
- breathing problems
- obstruction of the intestine from scar tissue

Results

Complete healing is expected without complications after bowel resection, but the period of time required for recovery from the surgery varies depending on the initial condition that required the procedure, the

WWW.BOOKBAZ.IR

patient's overall health status prior to surgery, and the length of bowel removed.

Morbidity and mortality rates

Prognosis for bowel resection depends on the seriousness of the disease. For example, primary treatment for colorectal cancer consists of wide surgical resection of the **colon cancer** and lymphatic drainage after the bowel is prepared. The choice of operation for **rectal cancer** depends on the tumor's distance from the anus and gross extent; overall surgical cure is possible in 70% of these patients. In the case of ulcerative **colitis** patients, the colitis is cured by bowel resection and most people go on to live normal, active lives. As for Hirschsprung's disease patients, approximately 70%–85% eventually achieve excellent results after surgery, with normal bowel habits and infrequent **constipation**.

Alternatives

Alternatives to bowel resection depend on the specific medical condition being treated. For most conditions where bowel resection is advised, the only alternative is medical treatment with drugs. In cases of cancer of the bowel, drug treatment alone will not cure the disease. Occasionally, it is possible to remove a rectal cancer from within the back passage without major surgery, but this only applies to very special cases. As for other conditions such as mild or moderate ulcerative colitis, drug therapy may represent an alternative to surgery; a combination of the drugs sulfonamide, sulfapyridine, and salicylate may help control inflammation. Similarly, most acute cases of **diverticulitis** are first treated with antibiotics and a liquid diet.

Bowel surgery with ostomy *see* **Colostomy**

Bowel training

Definition

Bowel training helps to reestablish normal bowel movements in persons who suffer from **constipation**, **diarrhea**, incontinence, or irregularity. Healthy bowel activity is considered one or two movements of moderate size every day.

Purpose

Many people for many reasons have irregular bowel function. In some cases, the irregularity lasts beyond the condition that caused it. The bowels by

themselves develop bad habits that can be retrained with suitable exercises and education. Normal bowel habits not only improve the quality of life, they help prevent several common diseases—for example, **diverticulitis** and fecal impaction. Gall stones, **appendicitis**, **colon cancer**, **hiatal hernia**, diabetes, and **heart disease** have also been related to the quality of bowel movements and the foods that affect them.

- One of the most common causes of constipation is the laxative habit. Repeated artificial stimulation of the bowels destroys their natural emptying reflex, so that they will no longer move without artificial stimulants. The laxative habit begins innocently enough with the correct belief that bowels should move every day; however, laxatives will cause the evacuation of several days worth of stool in a single movement. Impatient for stool to reaccumulate for the necessary few days, the patient takes another laxative, and the cycle begins.
- The other major cause of constipation is a diet with insufficient bulk or roughage. The bowel works more smoothly the more contents it has. Western diets of highly refined foods have eliminated most of the residue from food. The result is that most food is absorbed, leaving little to pass through and be excreted as feces.
- Constipation occurs acutely with impaction—the presence in the rectum of a mass of feces too large to pass. Fecal impaction is usually the result of poor bowel habits, a diet with too little liquid and roughage, and inadequate physical activity.
- Diarrhea, whether acute or chronic, can disrupt the bowel's normal rhythm and lead to irregularity.
- Several diseases of the nervous system affect bowel reflexes.

Description

Bowel training reestablishes the bowel's normal reflexes by repeating a routine until it becomes a habit. Naturally the patient must be able and willing to cooperate. Some patients are so convinced they need daily **laxatives** that they are afraid to do without them. It takes time for a changed diet to affect the bowels and for the bowel to regain its normal rhythm. Trust and patience are necessary.

After gaining the patient's cooperation, the next step is to optimize the diet. Healthy bowel movements require ingestion of a large amount of liquids and bulk foods. The patient should drink two to three quarts of liquids every day, with liberal inclusion of prune juice and perhaps coffee for their natural laxative effects. Bulk comes from unrefined foods. Oat bran, wheat bran, brown rice, green vegetables, apples, and pears are a few examples of high residue foods. Many patients will benefit from adding bulk preparations of psyllium. Constipating foods like bananas and cheese should be avoided until a natural rhythm is well established.

KEY TERMS

Defecate—To pass feces (stool) out of the rectum through the anus.

Diverticulitis—Infection of outpouchings in the large bowel.

Fecal impaction—Obstruction of the rectum by a large mass of feces (stool).

Hiatal hernia—Part of the stomach displaced through the diaphragm into the chest.

To assure that stools are soft enough to pass easily, it is a good idea to add a pure stool softener like DOSS (dioctyl **sodium** sulfosuccinate), two to four per day as needed. DOSS also helps prevent impaction.

There is usually a time of day when bowel movements are more likely to occur. In anticipation of this time, the patient should participate in activities that stimulate a normal bowel movement. Walking, eating unrefined foods, and drinking prune juice or coffee encourage natural evacuation. It is acceptable to use lubricants such as glycerine suppositories or oil **enemas** at this time. For severe constipation, water enemas may be needed to initiate a movement.

It is also important for the patient to recognize the urge to defecate and to respond right away to that urge. The longer stool sits in the rectum, the more water the rectum will absorb from it, making it harder and more difficult to pass.

Results

With patience and diligence, normal bowel habits and the health that comes with them will return in most patients.

Brachytherapy

Definition

Brachytherapy is a type of radiation therapy that involves placing small radioactive materials in or close to a tumor to destroy cancer cells.

Description

There are many ways to approach cancer treatment, and one of the more recent treatment choices for some cancers is brachytherapy. Also called interstitial radiation therapy, brachytherapy treats cancer inside the body, near or inside the cancerous tumor. Radioactive material is either directed at the cancer cells through tubes called catheters or implanted in a patient's body in tiny seeds or pellets.

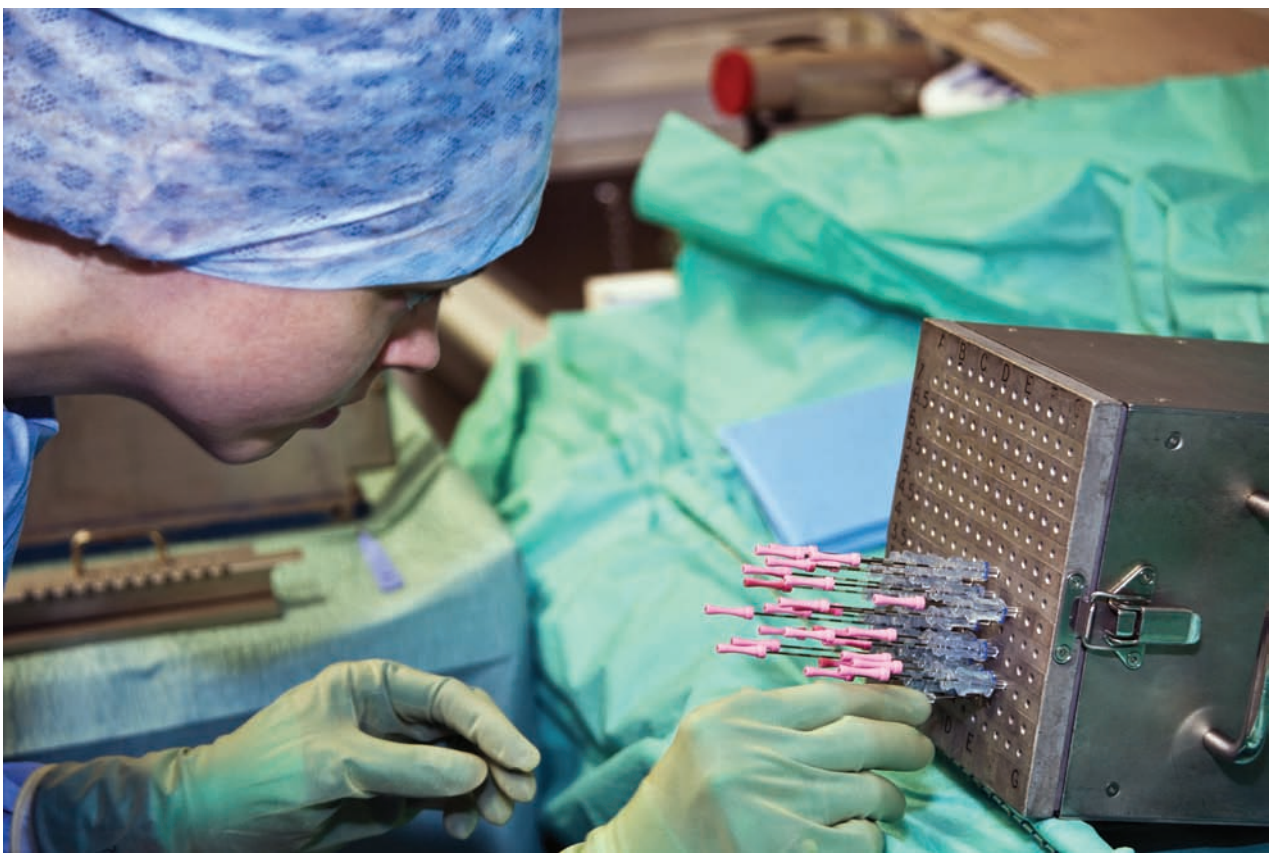
Radiation therapy

Radiation therapy is use of high-energy x rays, or radiation, to destroy cancer cells in a patient's body. Radiation therapy usually is used along with other treatments in managing cancer. For example, surgeons may operate to remove a cancerous tumor, and then have a patient undergo radiation therapy to make sure that any cancer cells remaining in the tissues around the margin, or border, of the tumor's location are destroyed. On the other hand, radiation therapy can shrink a very large tumor before a patient has surgery, making it easier for doctors to operate. Most radiation therapy is delivered from a machine that aims an x-ray beam from outside the patient's body to target the beam precisely.

Internal radiation therapy

Brachytherapy is not delivered from a beam outside the body, but instead delivers radiation inside a patient's body. The radioactive material is sealed inside another material, usually a seed, pellet, or ribbon. The exact type of radioactive material and delivery method depends on a patient's cancer and the size and location of the tumor.

High-dose-rate (HDR) brachytherapy usually involves a radiation oncologist placing a strong radiation



Brachytherapy is a radiotherapy that delivers radioactives sources to specific sites using long, hollow needles. The needles are positioned on a template grid to deliver precise irradiation of the targeted location. *(Antonia Reeve / Science Source.)*

source into the tumor using a flexible tube called a catheter. A radiation oncologist is a doctor who specializes in treating cancer using radiation. With low-dose-rate (LDR) brachytherapy, the radiation oncologist places a radiation source into the area of the tumor that will remain there for several days. Sometimes, the seed or implant remains in the patient permanently, although the radiation source decays with time.

During a brachytherapy procedure, s patient may receive an anesthetic medication through an intravenous (IV) line to relieve pain. Some patients receive a sedative or general anesthesia for heavier sedation. The type and amount of anesthesia depends on the location of the tumor being treated. Patients receiving general anesthesia are continuously monitored during the procedure. The radiation oncologist uses a thin tube called a catheter to guide the radiation seeds or ribbons to the tumor area. A small balloon or other holder also may be used. Some types of brachytherapy procedures require a brief hospital stay of a few days.

Purpose

Brachytherapy can deliver high doses of radiation to a tumor or organ, treating only the cells that have cancer instead of cells throughout the organ in which the tumor originated or throughout the body. For this reason, it is especially helpful for patients who have a localized cancer, or cancer that has not spread beyond the organ in which the tumor is found. The doctor can deliver a higher total dose of radiation in a shorter amount of time with brachytherapy, meaning fewer visits to the doctor for patients who have problems getting to the doctor because of physical limitations or distance from a facility.

Brachytherapy is used to treat several types of cancer, including cancer of the:

- prostate
- head and neck
- cervix and vagina
- uterus
- breast
- lung
- skin
- eye
- rectum
- gallbladder

Preparation

Patients having brachytherapy may need imaging or other examinations before the procedure to help doctors plan and prepare treatment. The exams and tests may include blood tests, an electrocardiogram, and imaging examinations such as computed tomography, ultrasonography, or magnetic resonance imaging (MRI). Patients may need to follow specific preparations based on the organ or area of the body being treated. For example, bowel preparation that cleanses the area for images the doctor uses to guide the procedure might be necessary for brachytherapy to treat rectal cancer.

Radiation therapy, including internal therapy, always involves careful planning and dosimetry. Dosimetry is the method used to measure radiation dosage for therapy. Treatment planning takes place a few days or weeks before the procedure to deliver or place the brachytherapy materials. A team of radiation therapists, medical physicists, dosimetrists, radiation therapists, and radiation oncology nurses may be involved in planning and delivering brachytherapy. The nurse, doctor, or therapist may provide additional instructions to prepare patients before the procedure. For example, if it is likely, or even possible, that a patient might need general anesthesia, instructions will include not drinking or eating within a certain number of hours before the procedure.

Aftercare

All radiation therapy can cause side effects, but the effects differ depending on the type of therapy and site. The doctor, nurse, or radiation therapist will discuss specific side effects to watch for following brachytherapy. These may include swelling or tenderness in the area where the radioactive sources were implanted or where the catheter was inserted. The team also will provide instructions for care after returning home. These instructions may include certain activities to avoid for a few days and recommendations to avoid close contact with children or pregnant women until the radioactive source begins to decay. This is particularly true with low-dose-rate implants, which may require limited visitation by friends and loved ones and a stay in a special hospital room until the implant is removed or the radioactive source decays to a safe level.

Brachytherapy requires follow-up appointments, partly to provide patients the opportunity to report side effects or concerns. These appointments also are necessary to check how well the treatment is working at eliminating cancer. Often, these appointments involve additional imaging to check actual dose received to the tumor and how well the treatment is working.

Risks

If a patient receives general anesthesia during a brachytherapy procedure, the same risks are present as

Impotence—The state in which a man cannot have sexual intercourse because of inability to maintain an erection.

Incontinence—The body's inability to control functions, usually urinary or bowel function.

with any anesthesia use. Some people have allergic reactions to medications used for sedation and anesthesia. Others have breathing problems when placed under general anesthesia. Because the catheter used to deliver brachytherapy enters a patient's skin, there is a slight risk of bleeding problems or infection.

In general, the levels of radiation used in brachytherapy are low enough that they cannot harm others. Patients who have concerns about implanted radiation should ask for more information. Occasionally, the radiation from brachytherapy can affect function of organs or tissues near the cancer. For example, some men who have brachytherapy for prostate cancer experience problems such as incontinence or impotence.

Brain abscess

Definition

Brain **abscess** is a bacterial infection within the brain.

Description

The brain is usually well insulated from infection by bacteria, protected by the skull, the meninges (tissue layers surrounding the brain), the immune system, and the highly regulated barrier between the bloodstream and the brain. Under certain circumstances, however, bacteria can invade the brain and cause a localized infection called an abscess. Brain abscess is relatively rare, accounting for 1 in 10,000 hospital admissions. Single abscess occurs in 75% of cases, and the remainder of cases involve multiple abscesses. If not treated, brain abscess is almost always fatal.

Causes and symptoms

One-half of all brain abscesses are caused by the spread of bacteria from a nearby infection. Sources of bacteria include:

- middle ear infections (otitis media) or infections in the bony spaces in front of the middle ear (mastoiditis)
- sinus infections
- an abscessed tooth

Other sources of bacteria include lung infections, abdominal infection, infection of the heart's lining (**endocarditis**), penetrating heart **wounds**, and **neurosurgery**.

Acquired immune deficiency syndrome (**AIDS**) or the presence of another immune deficiency greatly increases the risk of brain abscess. Approximately 25% of cases have no detectable cause of infection.

Brain abscess can be caused by a variety of organisms, many of them related to ear and sinus infections. Many times brain abscess cases are caused by two or more bacteria. In 30%–60% of cases, the bacteria combination includes streptococci, microorganisms that can live without oxygen (anaerobes), and enterobacteria. A small number of cases are caused by yeast, fungi, and single-cell organisms (protozoa).

The symptoms of brain abscess often develop slowly, usually within a period of about two weeks. The most common symptoms are:

- headache
- neurologic symptoms related to the specific part of the brain that is infected
- altered mental status
- seizures

KEY TERMS

Aspiration—Removal of fluid from a closed space through a needle.

Biopsy—The removal of a tissue sample for examination.

Diagnosis

Diagnosis of brain abscess is performed by using a computed tomography scan (CT) or a **magnetic resonance imaging** (MRI) scan to determine the site of infection. Tissue removal (biopsy) is usually performed as well. A biopsy is performed to determine the type of bacterium involved. Biopsies can also be used to rule out tumor or other noninfectious localized lesions, which may look the same on the scans.

Other tests are performed to determine the source of the infection. These tests include blood cultures, x rays of the chest, and a physical exam of the ears, sinuses, and teeth. A test for human **immunodeficiency** virus (HIV) is usually also performed.

Treatment

Treatment for brain abscess begins with intravenous **antibiotics**, chosen to match the infecting bacterium if known, or to cover a wide spectrum of possibilities if not. Treatment usually continues for six to eight weeks.

Aspiration surgery is almost always done to drain the abscess. In this procedure, a needle is guided to the infected site by CT scan, and fluid is removed (aspirated) from the abscess. Aspiration may be repeated several times until the bacteria are completely killed or removed. Surgical removal of infected or dead tissue may be needed in some cases. For patients with many sites of infection, aspiration or surgical removal is not done because of the increased difficulty and risk of the procedure. For these patients, antibiotic therapy alone is used. Steroid treatment is controversial, but may be indicated in some cases.

Prognosis

Even with prompt treatment, brain abscess is fatal in about 20% of cases. About half of those who survive have some residual neurological problems, including seizures in many patients.

There are several reasons why patients with brain abscess can have a poor prognosis. The illness may not be diagnosed correctly or an accurate diagnosis may take additional time. The patient may receive an antibiotic that does not match the infecting organism. Sometimes the infection may not be limited to a definite area in the brain, making diagnosis and treatment difficult. The small number of cases caused by fungal infection may take additional time to diagnose. A patient may also have a poor prognosis because there is more than one abscess, the location of the abscess is deep within the brain, or the infection has moved into many locations within the brain. Severe complications can result from brain abscess, including comma and brain rupture. In 80%–100% of cases involving brain rupture, the patient dies.

Prevention

Brain abscess may be preventable by prompt and aggressive treatment of the infections that give rise to it, especially sinus and ear infections.

Brain biopsy

Definition

A brain biopsy is the removal of a small piece of brain tissue for the diagnosis of abnormalities of the brain, such as Alzheimer's disease, tumors, infection, or inflammation.

Purpose

By examining the tissue sample under a microscope, the biopsy sample provides doctors with the information necessary to guide diagnosis and treatment.

Precautions

Imaging of the brain is performed to determine the precise positioning of the needle to enter the brain.

Description

When an abnormality of the brain is suspected, stereotactic (probing in three dimensions) brain needle biopsy is performed and guided precisely by a computer

WWW.BOOKBAZ.IR

KEY TERMS

Alzheimer's disease—A progressive, neurodegenerative disease characterized by loss of function and death of nerve cells in several areas of the brain, leading to loss of mental functions such as memory and learning.

Computed axial tomography (CT)—An x-ray technique that has the ability to image soft tissue, bone, and blood vessels.

Cortex—The thin, convoluted surface of the brain composed primarily of cell bodies of neurons.

Magnetic resonance imaging (MRI)—An imaging technique that uses radiowaves, magnetic fields, and computer analysis to visualize body tissue and structures.

Stereotactic brain needle biopsy—A procedure in which a computer uses information from a CT or MRI to create a three-dimensional map of the operation site to better guide the needle to perform the biopsy.

system to avoid serious complications. A small hole is drilled into the skull, and a needle is inserted into the brain tissue guided by computer-assisted imaging techniques (CT or MRI scans). Historically, the patient's head was held in a rigid frame to direct the probe into the brain; however, since the early 1990s it has been possible to perform these biopsies without the frame. Since the frame was attached to the skull with screws, this advancement is less invasive and better tolerated by the patient. The doctor (pathologist) prepares the sample for analysis and studies it further under a microscope.

Preparation

A CT or MRI brain scan is done to find the position where the biopsy will be performed. Prior to the biopsy, the patient is placed under general **anesthesia**.

Aftercare

The patient is monitored in the recovery room for several hours and is usually required to spend a few days in the hospital since general anesthesia is required.

Risks

The procedure is invasive and includes risks associated with anesthesia and surgery. Brain injury may occur due to removal of brain tissue. The resulting scar left on the brain has the potential to trigger seizures.

Results

Normal results

After examining the brain tissue directly, no abnormalities are detected.

Abnormal results

Various brain abnormalities can be diagnosed by microscopic analysis of the tissue sample. The pathologist (a physician trained in how disease affects the body's tissues) looks for abnormal growth, changes in cell membranes, and/or abnormal collections of cells. In Alzheimer's disease, the cortex of the brain contains abnormal collections of plaques. If infection is suspected, the infectious organism can be cultured from the tissue and identified. Classification of tumors is also possible after biopsy.

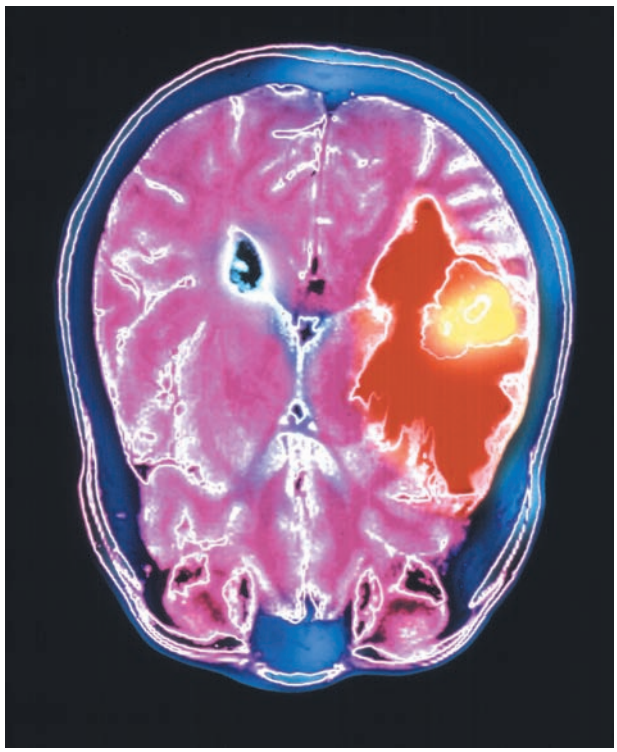
Brain tumor

Definition

A brain tumor is an abnormal growth of tissue in the brain. Unlike other tumors, brain tumors spread by local extension and rarely metastasize (spread) outside the brain. A benign brain tumor is composed of noncancerous cells and does not metastasize beyond the part of the brain where it originates. A brain tumor



Magnetic resonance imaging (MRI) scan of axial section of human brain showing a metastatic tumor (yellow in image). *(© Simon Fraser/Science Photo Library/Photo Researchers, Inc.)*

is considered malignant if it contains cancer cells, or if it is composed of harmless cells located in an area where it suppresses one or more vital functions.

Demographics

Each year, more than 22,000 malignant brain tumors are diagnosed in adults and children in the United States, according to the American Cancer Society. An estimated 13,000 people died from brain tumors in the United States in 2009. Brain tumors can develop at any age but are most commonly diagnosed in children between the ages of 3–12 and in adults aged 55–65. The overall risk for developing a malignant brain tumor is less than 1%.

Description

Risk factors

Primary tumors of the brain and central nervous system are often associated with HIV infection. Men and Caucasians tend to have a higher risk of developing brain tumors. Individuals considered at high risk for the development of brain cancer include children with a history of previous radiation treatment to the head for cancer and patients with certain cancers (nervous system, salivary gland, colon). Other risk factors include having an older father; occupational exposure to vinyl chloride, lead, and pesticides; history of **epilepsy**; and a history of certain genetic conditions (tuberous sclerosis, **neurofibromatosis**, von Hippel Lindau, **familial polyposis**, Osler-Weber-Rendu, Li-Fraumeni).

About half of all primary brain tumors are benign but in life-threatening locations. The rest are malignant and invasive.

Benign brain tumors

Benign brain tumors, composed of harmless cells, have clearly defined borders, can usually be completely removed, and are unlikely to recur. Benign brain tumors do not infiltrate nearby tissues but can cause severe **pain**, permanent brain damage, and death. Benign brain tumors sometimes become malignant.

Malignant brain tumors

Malignant brain tumors do not have distinct borders. They tend to grow rapidly, increasing pressure within the brain (IICP) and can spread in the brain or spinal cord beyond the point where they originate. It is highly unusual for malignant brain tumors to spread beyond the central nervous system (CNS).

Primary brain tumors

Primary brain tumors originate in the brain. They represent about 1% of all cancers and 2.5% of all cancer deaths.

Metastatic or secondary brain tumors

Metastatic brain tumors are much more common than primary brain tumors with more than 100,000 patients per year in the United States dying from the effects of metastatic brain tumors. As many as 25% of all cancer patients develop secondary or metastatic brain tumors when cancer cells spread from another part of the body to the brain. Secondary brain tumors are most apt to occur in patients who have:

- breast cancer
- colon cancer
- kidney cancer
- lung cancer
- melanoma (cancer) of the skin; these metastatic brain tumors can develop on any part of the brain or spinal cord

WWW.BOOKBAZ.IR

- cancer within the nasal passages and/or throat, which could follow the nerve pathways into the skull and metastasize to the brain

Naming and grading brain tumors

The name of a brain tumor describes where it originates, how it grows, and what kind of cells it contains. A tumor in an adult is also graded or staged according to:

- how malignant it is
- how rapidly it is growing and how likely it is to invade other tissues
- how closely its cells resemble normal cells (the more abnormal a tumor cell looks, the faster it is likely to grow)

Low-grade brain tumors usually have well-defined borders. Some low-grade brain tumors form or are enclosed (encapsulated) in cysts. Low-grade brain tumors grow slowly, if at all. They may spread throughout the brain, but rarely metastasize to other parts of the body.

Mid-grade and high-grade tumors grow more rapidly than low-grade tumors. Described as "truly malignant," these tumors usually infiltrate healthy tissue. The growth pattern makes it difficult to remove the entire tumor, and these tumors recur more often than low-grade tumors.

A single brain tumor can contain several different types of cells. The tumor's grade is determined by the highest-grade (most malignant) cell detected under a microscope, even if most of the cells in the tumor are less malignant. An infiltrating tumor is a tumor of any grade that grows into surrounding tissue.

Types of brain tumors

Glioma is the term used to refer to the most prevalent primary brain tumors. Gliomas arise from glial tissue, which supports and nourishes cells that send messages from the brain to other parts of the body. These tumors may be either malignant or benign. Astrocytomas, ependymomas, and mixed gliomas are three of the most common gliomas.

ASTROCYTOMAS. Named for the star-like shape of their cells, astrocytomas can develop on any part of the brain or spinal cord. Non-infiltrating astrocytomas grow slowly, and rarely spread to nearby tissue. Mild-to-moderately anaplastic astrocytomas with well-differentiated borders do not grow as slowly as non-infiltrating astrocytomas, and they do spread to surrounding tissues.

Anaplastic astrocytomas, which are also called Grade III astrocytomas, look more abnormal and grow more rapidly than non nfiltrating or mild-to-moderately anaplastic tumors.

Grade IV astrocytomas are also called glioblastoma multiforme (GBM) tumors. Accounting for 30% of all primary brain tumors, GBMs are the most common brain tumors in middle-aged adults. GBMs are the most malignant of all brain tumors. They contain a greater mixture of cells than any other brain tumors making them the most difficult to treat.

EPENDYMOMAS. Also called ependymal tumors, ependymomas account for 9% of all gliomas, and 5% of all intracranial tumors. These tumors, which are most common in children and adolescents, begin in the very thin membranes that help form cerebrospinal fluid (CSF) and line the brain cavities (ventricles) that contain it.

Ependymomas are usually benign, have well-differentiated borders, resemble normal cells, and grow very slowly. The cells of anaplastic (malignant) ependymomas look abnormal and grow more rapidly than the cells of benign tumors.

MIXED GLIOMAS. Heterogeneous tumors containing elements of astrocytomas and ependymomas and/or oligodendrogliomas are called mixed gliomas. These are rare tumors that usually occur in middle-aged adults, grow slowly, and do not usually spread beyond the part of the brain where they originate. Mixed gliomas behave like tumors composed of the highest-grade cells they contain.

Non-glial brain tumors

The most common brain tumors that do not develop from glial cells are medulloblastomas, meningiomas, and Schwannomas.

MEDULLOBLASTOMAS. Scientists once thought medulloblastomas (MDLs) developed from glial cells. These fast-growing, malignant tumors are now believed to originate in developing cells not normally present in the body after birth. They are sometimes called primitive neurodectal tumors (PNET).

MDL tumors are most common in children and are more common in boys than in girls. Only 30% of MDL tumors occur in adults. MDL tumors usually originate in the cerebellum (the part of the brain that controls coordination and some muscle activity) and are often carried to other parts of the brain by cerebrospinal fluid. MDL tumors rarely metastasize beyond the brain and spinal cord.

MENINGIOMAS. Meningiomas, which represent more than 20% of all primary brain tumors, originate in the membranes that enclose the brain and spinal cord (meninges). These tumors are usually benign and most often occur in women aged 30–50 years old. Meningiomas grow so slowly that the brain can sometimes become accustomed to their presence. Meningiomas compress, rather than invade, brain tissue and may grow to be quite large before any symptoms appear.

SCHWANNOMAS. Schwannomas originate in the Schwann cells. These cells produce myelin, the material that protects the acoustic nerve, which controls hearing. These benign tumors are twice as common in women as in men, and are most often diagnosed in patients between the ages 30–60.

Schwannomas grow very slowly, and many people adapt to the slight **hearing loss** and balance problems that are the tumors' earliest symptoms. A pear-shaped Schwannoma can cause sudden or gradual loss of hearing in an ear. As the tumor progresses, it can press on the nerves that control movement and feeling in the face and cause headaches and facial numbness or tingling. The patient may have trouble walking, swallowing, or controlling eye movements, and the sense of taste can be affected. A Schwannoma that grows large enough to press on the brain stem can be deadly.

Gliomas, meningiomas, pituitary adenomas, acoustic neuromas, and metastatic brain tumors constitute about 95% of all brain tumors.

CHILDHOOD BRAIN TUMORS. Brain tumors that occur in children are described as supratentorial (in the upper part of the brain) or infratentorial (in the lowest part of the brain). Astrocytomas and ependymomas are common supratentorial tumors. Infratentorial tumors include medulloblastomas, astrocytomas, and ependymomas.

Causes and symptoms

The cause of primary brain tumors is unknown, but people who work with rubber and certain chemicals have a greater-than-average risk of developing them. There is no evidence that **head injury** causes brain tumors, but researchers are trying to determine the relationship, if any, between brain tumors and viruses, family history, and long-term exposure to electromagnetic fields.

Results of an international study released in 2010 concluded there was no increased risk of developing glioma or meningioma in people who use mobile phones. However, the researchers cautioned that additional research in this area is needed, particularly as it relates to heavy users of mobile phones.

KEY TERMS

Central nervous system (CNS)—The division of the nervous system that consists of the brain and spinal cord.

Cerebrospinal fluid (CSF)—Clear liquid that fills brain cavities and protects the brain and spinal cord.

Gamma knife—High-dose radiation treatment for intracranial tumors.

Intracranial—Located within or on the surface of the brain.

Symptoms do not usually appear until the tumor grows large enough to displace, damage, or destroy delicate brain tissue. When that happens, the patient may experience:

- headaches that become increasingly painful and are most painful when lying down
- nausea and vomiting or sudden attacks of vomiting not accompanied by nausea
- seizures
- dizziness or loss of coordination or balance
- personality changes
- sudden loss of vision
- memory loss
- speech problems
- sensory changes
- mental impairment
- weakness or paralysis on one side of the body

A doctor should be notified whenever a patient experiences one or more of these symptoms.

Diagnosis

Although brain tumor symptoms resemble those of many other illnesses, the presence of a brain tumor may be indicated by:

- persistent headaches with vomiting or convulsions
- progressive deterioration of sight, speech, hearing, or touch, or deterioration in the ability to use an arm, hand, foot, or leg

Examination

When a patient experiences one or more symptoms, a primary care physician will perform a complete

WWW.BOOKBAZ.IR

physical examination, take a detailed medical history, and conduct a basic neurologic examination to evaluate:

- balance and coordination
- abstract thinking and memory
- eye movements
- hearing, touch, and sense of smell
- reflexes
- control of facial muscles and movements of the head and tongue
- awareness

Tests

If the results of the examination suggest a patient may have a brain tumor, a neurologist will recommend some or all of these additional diagnostic tests:

- computed tomography scan (CT scan) to reveal brain abnormalities
- magnetic resonance imaging (MRI) to detect tumors beneath the bones of the skull
- perfusion MRI to detect the pattern of blood flow in the brain
- complex imaging techniques such as positron emission tomography (PET scan) or single photon emission computed tomography (SPECT scan)
- electroencephalography (EEG) to measure electrical activity in the brain
- x rays to reveal any distortion in the bones of the skull
- angiography to outline a tumor and the blood vessels that lead to it
- a brain scan to identify and record the location of abnormal cells in the brain
- radionuclide brain scintigraphy to view the capillaries feeding the tumor after highlighting them with a radioactive substance
- myelography (x ray of the spine) to detect a spinal cord tumor
- a lumbar puncture (spinal tap) to obtain spinal fluid, which may contain tumor cells

Procedures

Interpreting these images and results of laboratory analysis allows neurologists to determine whether a tumor is present, but microscopic examination of tumor tissue (biopsy) is the only way to identify the kind of cells it contains.

Treatment

Brain tumors are treated by multidisciplinary teams of highly skilled specialists whose decisions are based on the following:

- results of diagnostic tests
- tumor size, position, and growth pattern
- the patient's health history and current medical status
- the wishes of the patient and his family

Traditional

SURGERY. Surgery is the treatment of choice for accessible brain tumors that can be removed without causing serious neurologic damage. The procedure most often performed is a **craniotomy**, but the goals of any type of brain tumor surgery include:

- removing as much of the tumor as possible (called debulking the tumor)
- removing tumor tissue for microscopic analysis
- allowing neurosurgeons to see exactly how the tumor is situated and how it is growing
- creating an entry channel for chemotherapy drugs and forms of radiation that are implanted in the brain

Depending on the type of brain tumor, its location, and its size, a number of different techniques may be used to surgically remove it. Surgical techniques include:

- classic operation
- laser microsurgery (uses high temperatures to vaporize tumor cells
- ultrasonic aspiration (uses ultrasound waves to break up the tumor into smaller bits that can be "vacuumed" out

Before undergoing brain surgery, patients are often given **steroids** to reduce swelling of brain tissue and/or undergo radiation treatments to reduce tumor size. Anticonvulsant medications may be prescribed to prevent or control seizures.

Patients whose benign brain tumors can be completely removed may not require any additional treatment, but periodic physical and neurologic examinations and CT or MRI scans are sometimes recommended to determine whether the tumor has returned. Because surgeons cannot be sure that every bit of an infiltrating or metastasizing tumor has been removed, radiation and **chemotherapy** are used to eradicate cells that may have escaped the scalpel.

If a tumor cannot be completely removed, removing a portion of it (debulking) can alleviate the patient's symptoms, enhance the sense of well-being, and increase the effectiveness of other treatments.

RADIATION THERAPY. External radiotherapy, generally delivered on an outpatient basis, directs radiation to the tumor and the area around it. Newer techniques are used to ensure that radiation is targeted as precisely as possible to the tumor. These techniques include three-dimensional conformal **radiation therapy** (3D-CRT), intensity modulated radiation therapy (IMRT), and conformal proton beam radiation therapy.

Implant radiation therapy involves placing tiny pieces of radioactive material in the brain. Left in place permanently, or for a short time, these radioactive pellets release measured doses of radiation each day. This technique is called brachytherapy.

Brachytherapy and external beam radiation therapy may be used concurrently to treat the tumor.

Stereoactic radiosurgery involves fitting the patient with a frame to stabilize the head, using imaging techniques to determine the exact location of tumor cells, and using a sophisticated instrument to administer radiation precisely to that point. Methodologies used for delivery of radiation by this technique include particle beam therapy, photon-based therapy (Gamma Knife), and the movable linear accelerator (X-Knife, Cyberknife, and Clinac).

A variety of drugs may also be given during radiation therapy to protect brain cells from the effects of radiation (radioprotective drugs), to increase the sensitivity of tumor cells to radiation (radiosensitizers), or to boost radiation's effects (radioenhancers).

Drugs

CHEMOTHERAPY. One or more cancer-killing drugs may be taken by mouth or injected into a blood vessel or the cerebrospinal fluid. Chemotherapy may be used with radiation and surgery as part of a patient's initial treatment, or used alone to treat tumors that recur in the same place or in another part of the body. The usual chemotherapy regimen for a brain tumor is a combination approach. Chemotherapy drugs commonly used in the treatment of brain cancers include procarbazine, lomustine (CCNU), carmustine (BCNU), temozolomide, carboplatin, cisplatin, etoposide, irinotecan, methotrexate, and vincristine.

New methods of delivering chemotherapy are being used as well. These include:

- intrathecal chemotherapy, which instills the medications right into the spinal fluid;
- intra-arterial chemotherapy, which uses tiny catheter tubes to delivery high-dose chemotherapy directly into the arteries of the brain;
- interstitial chemotherapy, which is performed at the time of surgery. A chemotherapy-soaked wafer, carmustine (Gliadel), is placed in the cavity left after tumor removal.

Potentially toxic chemotherapy drugs can be wrapped in special biologic envelopes called liposomes, to allow the drugs to be delivered to the tumor without adversely affecting other healthy tissues along the way.

When a young child has a brain tumor, chemotherapy is often used to eliminate or delay the need for radiation.

Targeted therapy

Therapies are being developed that target specific proteins on tumor cells. A type of targeted therapy used in the treatment of glioblastoma is the monoclonal antibody bevacizumab (Avastin).

Other treatments

If a brain tumor cannot be cured, treatment is designed to make the patient as comfortable as possible and preserve as much of his neurologic functioning as possible. The patient's doctor may prescribe:

- analgesics to relieve pain
- anticancer drugs to limit tumor growth
- anticonvulsants to control seizures
- steroids to reduce swelling of brain tissue

Alternatives

Alternative treatments have not been shown to cure brain tumors and should never be substituted for conventional therapy. However, complementary therapies (used with, not instead of, standard treatments) can help some patients cope with the **stress** of their illness and side effects of their treatment.

Massage, **meditation**, and **reflexology** help some patients relax, while **yoga** is said to soothe the body, spirit, and mind. **Hydrotherapy** uses ice, liquid, and steam to improve circulation and relieve pain. **Therapeutic touch** practitioners say they can relieve pain and other symptoms by moving their hands in slow, rhythmic motions several inches above the patient's body.

Botanical therapies, homeopathic treatment, **traditional Chinese medicine** treatments, nutritional focuses on diet and supplements, and **detoxification** can also be incorporated as complementary therapies.

Prognosis

The patient's prognosis depends on where the tumor is located, what type of cells it contains, the

WWW.BOOKBAZ.IR

size of the tumor, and the effect it has already had on adjacent brain structures. A patient whose tumor is discovered early and removed completely may make a full recovery, but the surgery itself can harm or destroy normal brain tissue, causing:

- problems with thought, speech, and coordination
- seizures
- weakness
- personality changes

Although these post-operative problems may initially be more severe than the symptoms produced by the tumor, they can potentially diminish or disappear in time.

Occupational therapy can teach patients and their families new ways to approach daily tasks. **Physical therapy** can benefit patients who have difficulty keeping their balance, expressing their thoughts, speaking, or swallowing. Children may need special tutors before and after returning to school. For patients who have incurable brain tumors, hospice care may be available. Hospices provide a supportive environment and help patients manage pain and remain comfortable.

Inoperable tumors

Brain tumors that cannot be removed may cause irreversible brain damage and death.

Prevention

The cause of primary brain tumors has not been determined, so there is no known way to prevent them.

The best way to prevent secondary or metastatic brain tumors is to eliminate such risk factors as the following:

- poor nutrition and a low-fiber diet, since these contribute to development of intestinal cancers that can metastasize to the brain
- smoking, which causes lung cancer
- excessive use of alcohol, which is associated with liver cancer
- excessive exposure to the sun, which can cause melanoma (a deadly form of skin cancer)

Monthly self-examinations of the breasts and testicles can detect breast and **testicular cancer** at their earliest, most curable stages.

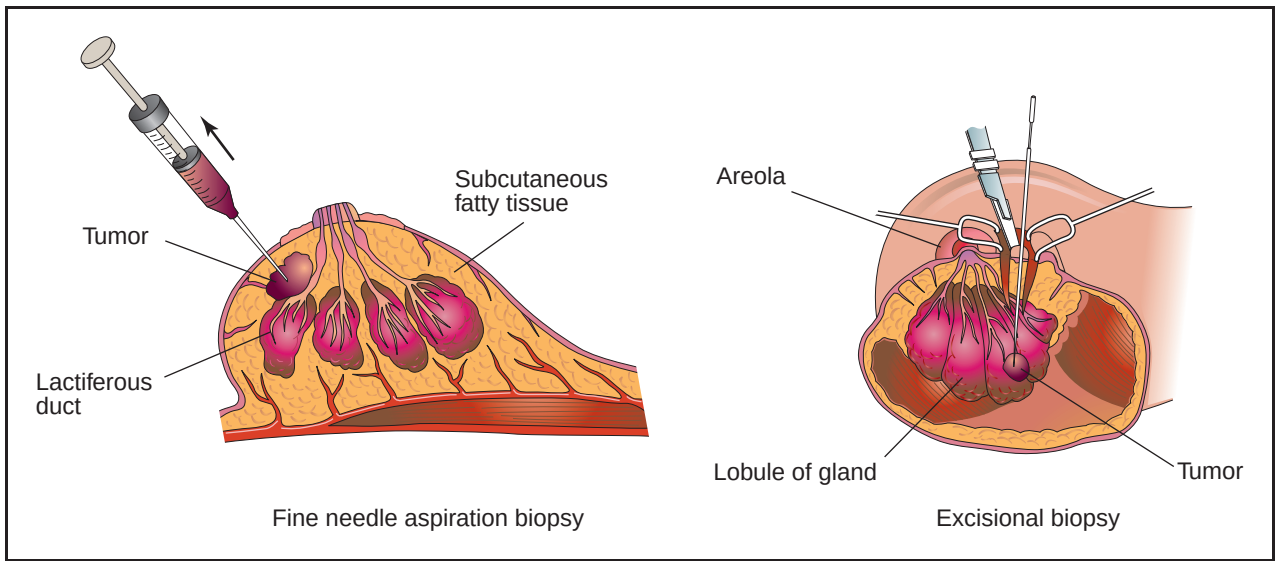
Breast biopsy

Definition

A breast biopsy is removal of breast tissue for examination by a pathologist. This can be accomplished surgically, or by withdrawing tissue through a needle.

Purpose

A biopsy is recommended when a significant abnormality is found, either on **physical examination**



A fine needle aspiration biopsy uses a very thin needle to withdraw fluid and cells from the breast to be examined. An excisional biopsy is a surgical procedure in which the entire area of concern and some surrounding tissue is removed for analysis. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

and/or by an imaging test. Examples of abnormality can include a breast lump felt during physical self-examination or tissue changes noticed from a mammogram test. Before a biopsy is performed, it is important to make sure that the threat of cancer cannot be disproved or ruled out by a simpler, less invasive examination. A lump may be obviously harmless when examined by **ultrasound**. If this is not decisive, the presence of cancer or a variety of benign breast conditions can be determined using a biopsy.

Precautions

The type of biopsy recommended should be considered. This will depend on whether the area can be felt, how well it can be seen on mammogram or ultrasound, and how suspicious it feels or appears. Specialized equipment is needed for different types of biopsy and availability may vary. Generally, needle biopsy is less invasive than surgical biopsy. It is appropriate for most, but not all, situations. However, some surgeons feel it is far less accurate.

Description

Surgical biopsy

If an abnormality is not felt during a self-examination, there are signs that indicate the need for medical attention. These include:

- severe breast pain
- changes in the size of a breast or the nipple
- changes in the shape of both breast or nipple
- pitting, dumpling, or redness of the breast skin
- nipple redness, irritation, or inversion
- changes in the pattern of veins visible on the surface of the breast
- some types of nipple discharge

If the abnormality is not felt, a needle localization must be done before the actual surgery. After local anesthetic is administered, a fine wire is placed in the area of concern. Either x ray or ultrasound guidance is used. The patient is awake and usually sitting up.

There are two types of breast biopsy considered here, excisional and incisional. An excisional biopsy is a surgical procedure, where the entire area of concern and some surrounding tissue is removed. It is usually done as an outpatient procedure in a hospital or free-standing surgery center. The patient may be awake, and is sometimes given medication to induce drowsiness. The area to be operated on is numbed with local anesthetic. Infrequently, general **anesthesia** is used.

An excisional biopsy itself usually takes under one hour. The total amount of time spent at the facility depends on the type of anesthesia used, whether a needle localization was done, and the extent of the surgery.

If a mass is very large, an incisional biopsy may be performed. In this case only a portion of the area is removed and sent for analysis. The procedure is the same as an excisional biopsy in other respects.

WWW.BOOKBAZ.IR

KEY TERMS

Fine needle aspiration biopsy—A procedure using a thin needle to remove fluid and cells from a lump in the breast.

Large core needle biopsy—A procedure using a thicker needle to remove a core of tissue, about the size of a grain of rice, from the breast.

Needle biopsy

A needle biopsy removes part of the suspicious area for examination. There are two types, aspiration biopsy (using a fine needle), and large core needle biopsy. Either of these may be called a percutaneous needle biopsy. Percutaneous refers to a procedure done through the skin.

A fine needle aspiration biopsy uses a very thin needle to withdraw fluid and cells that can be studied. It can be done in a doctor's office, clinic, or hospital. Local anesthetic may be used but is sometimes withheld, as it may be more painful than the biopsy needle. The area to place the needle may be located by touch. No specialized equipment is needed. However, using ultrasound guidance enables the physician to feel and see the lesion at the same time. The actual withdrawing of fluid and cells can be visualized as it occurs. This helps ensure that the specimen is taken from the right place.

A large core needle biopsy uses a larger diameter needle to remove small pieces of tissue, about the size of a grain of rice. It can be done in a clinic or hospital that has the appropriate facilities. Local anesthetic is routinely used. Ultrasound or x ray is used for guidance of a large core needle biopsy.

If the suspicious area is seen best with x ray, a stereotactic device is used. This means that x rays are taken from several angles. This information is fed into a computer, which analyzes the data and guides the needle to the correct place. The patient may be sitting up, or she may be lying on her stomach, with her breast positioned through an opening in the table. The breast is held firmly but comfortably between a plastic paddle and a metal plate, similar to those used for mammograms (a set of x rays taken of the front and side of the breast). X rays may be taken before, during, and after the tissue is drawn into the needle, to confirm that the correct spot is biopsied. This procedure may also be referred to as a stereotactic core biopsy, or a mammotomy.

Ultrasound is used to guide needle placement for some lesions. The patient lies on her back or side. After the area is numbed, sterile gel is applied. The physician places a transducer, an instrument about the size of an electric shaver, over the skin. This produces an image from the reflection of sound waves. A special needle, usually in a spring-loaded device, is used to obtain the tissue. The procedure is observed on a monitor as it is happening.

Preparation

A surgical breast biopsy may require the patient to have nothing to eat or drink for a period of time before the operation. This will typically be from midnight the night before, if general anesthesia is planned. No food restrictions are necessary for needle biopsy. It is advisable to eat lightly before the procedure. This is especially important if the patient will be lying on her stomach for a stereotactic biopsy.

Aftercare

After a surgical biopsy, the incision will be closed with stitches and covered with a bandage. The bandage can usually be removed in one or two days. Stitches are taken out approximately one week afterward. Depending on the extent of the operation, normal activities can be resumed in approximately one to three days. Vigorous **exercise** may be limited for one to three weeks.

The skin opening for a needle biopsy is minimal. It may be closed with thin, clear tape, called a steri strip, or covered with a bandaid and a small gauze bandage. The patient can return to her usual routine immediately after the biopsy. Strenuous activity or heavy lifting is not recommended for 24 hours. Any bandages can be removed one or two days after the biopsy.

Risks

Infection is always a possibility when the skin is broken, although this rarely occurs. Redness, swelling, or severe **pain** at the biopsy site would indicate a possible infection. Another possible consequence of a breast biopsy is a hematoma. This is a collection of blood at the biopsy site. It is usually absorbed naturally by the body. If it is very large and uncomfortable, it may need to be drained. A surgical breast biopsy may produce a visible scar on the breast. Sometimes this may make future mammograms harder to interpret accurately.

A false negative pathology report is another risk. This means that no cancer was found when a cancer was present. The incidence of this varies with the biopsy technique. In general, fine needle aspiration biopsies have the highest rate of false negative results, but there may be variation in results between facilities.

Results

A normal pathology report indicates no malignancy is present. The tissue sample may be further classified as a benign breast condition, such as tumor of the breast (**fibroadenoma**) or connective tissue that resembles fiber (fibrosis). Studies have demonstrated that approximately 80% of all breast biopsies result in a benign pathology report.

An abnormal pathology report indicates a cancer is present. If a fine needle aspiration biopsy was performed, the pathologist has viewed individual cells under a microscope to see if they appear cancerous. Large core needle biopsy and surgical biopsy will be able to give more information. This includes the type of cancer, whether it has invaded surrounding tissue, and how likely it is to spread quickly. There are some conditions that are not malignant but indicate high risk for future development of **breast cancer**. If these are identified, more frequent monitoring of the area may be recommended.

Breast cancer

Definition

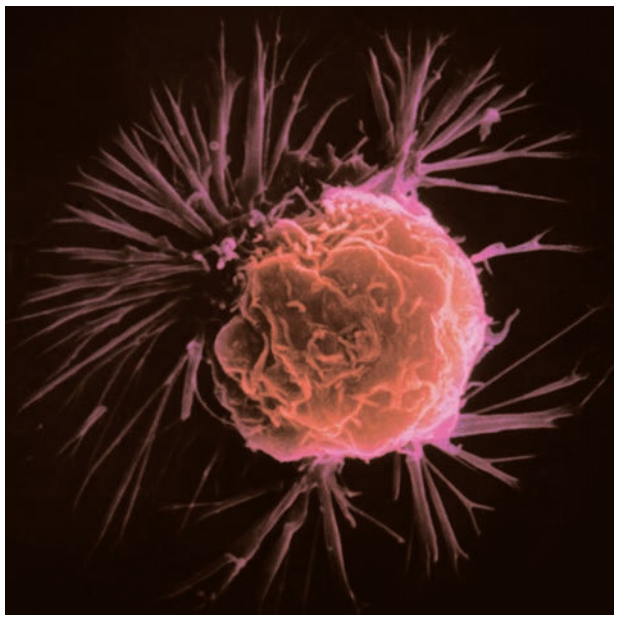
Breast cancer is the uncontrolled proliferation of abnormal cells originating in breast tissue, usually in the lining of the milk ducts or in the milk glands, leading to tumor formation. The cancer cells may invade nearby normal tissue or spread (metastasize) throughout the body.

Demographics

Breast cancer is the second most common cancer among American women, after **skin cancer**, accounting for almost one in three cancers diagnosed in women. One in eight women is likely to be diagnosed with breast cancer during her lifetime. It is the second most common cause of cancer death among women in the United States, after lung cancer. Approximately 232,000 new cases of invasive breast cancer were expected to be diagnosed among American women in 2013, and 40,000 women were expected to die of the disease. As of 2013, almost 3 million American women had previous or ongoing breast cancer. Both new diagnoses and deaths from breast cancer declined in the 1990s and early 2000s, as a result of earlier diagnosis with screening mammograms, improved therapies, and a dramatic decrease in the use of **hormone replacement therapy** (HRT) by postmenopausal women. Male breast cancers account for about 1% of breast cancer diagnoses in the United States. Approximately 2,240 new cases and 410 deaths from male breast cancer were expected in 2014.

Breast cancer most often develops between the ages of 50 and 70. Almost 80% of breast cancer diagnoses and 90% of deaths are in women over 50. African American women are 40% more likely to die of

WWW.BOOKBAZ.IR



A breast cancer cell. *(© NIH/Phototake.—All rights reserved.)*

breast cancer than Caucasian women. This higher death rate is believed to be due to lack of screening and early detection, as well as less overall health care and inferior cancer care.

Description

Most breast cancers are ductal carcinomas originating in the lining of milk ducts, the tubes that carry milk from the milk-producing glands (lobules) to the nipple. Lobular carcinoma begins in the milk glands. Rarely, breast cancer originates in other breast tissues. Invasive breast cancer spreads from the ducts or lobules to surrounding breast tissues. Breast cancer *in situ* is an early malignancy. Untreated ductal carcinoma in situ (DCIS), or intraductal carcinoma, may become invasive. Lobular carcinoma in situ (LCIS) represents an increased risk for invasive cancer in one or both breasts.

Breast cancer occurs by different mechanisms. Estrogen receptor (ER)-positive breast cancer cells have receptors on their surfaces for the female hormone estrogen and proliferate in response to estrogen. HER2-positive breast cancers have too many copies of the gene HER2 that codes for the human epidermal growth factor receptor 2, which normally regulates cell growth, division, and repair. Multiple copies of HER2 cause the cells to grow out of control. In the past, HER2-positive breast cancers were more aggressive and more likely to recur after treatment; however, targeted treatments may have reduced these risks. Triple-negative breast cancer is an aggressive type that is more difficult to treat, because the cancer cells lack both estrogen and progesterone receptors and do not have excess HER2.

Metastatic breast cancer

Invasive breast cancer may spread beyond the breast to nearby lymph nodes or metastasize to other organ systems and become systemic. Lymph is the clear, protein-rich fluid that travels through the lymphatic system, bathing cells throughout the body and eventually returning to the bloodstream. Along the way, lymph is filtered through lymph nodes. Most organs in the body have a primary lymph node group that filters fluid from that organ. The primary lymph nodes for the breasts are the axillary nodes under the armpits. Breast cancer typically spreads first from the breast to these axillary nodes, called regional metastasis. Cancer cells may then spread to other parts of the body through the bloodstream.

By the time a woman can feel a cancerous lump in her breast, it is often 0.4 in. (1 cm) in size, contains about one million cells, and may have been developing for one to five years. By then, cancer cells may already have spread through the lymph or blood. The presence and number of regional lymph nodes containing cancer cells is the single best indicator of whether or not the cancer has begun to widely metastasize. Breast cancers typically metastasize to the lungs, bones, liver, skin, and soft tissues. Death from breast cancer is usually caused by cancer that has spread and compromised the functions of vital organs.

Risk factors

Female risk of breast cancer rises dramatically with age. A woman who lives to age 85 has a 12% risk of developing breast cancer during her lifetime. Other risk factors include:

- a family history of breast, uterine, ovarian, or colon cancer, especially in a premenopausal mother or sister
- common mutations in the BRCA1 or BRCA2 genes, which account for 5–10% of breast cancers and confer a breast cancer risk of up to 80%
- previous abnormal breast biopsies or breast cancer
- first menstruation before age 12 or entering menopause after age 55
- never having children, having a first child after age 30, or never having breast fed
- alcohol, especially daily alcohol consumption of two or more drinks

Breast cancer

- An estimated 232,670 female breast cancer cases were diagnosed in 2014.
- An estimated 2,360 male breast cancer cases were diagnosed in 2014.
- The lifetime risk of developing invasive breast cancer is 1 in 8 in females and 1 in 1,000 in males.
- In 2014, there were more than 2.8 million breast cancer survivors living in the United States.

SOURCE: American Cancer Society, "What are the key statistics about breast cancer?" and "What are the key statistics about breast cancer in men?" Available online at http://www.cancer.org/ index (accessed September 5, 2014).

(Table by PreMediaGlobal. © Cengage Learning®.)

- overweight, obesity, or a high-fat diet
- breast exposure to radiation as a child or young adult for treatment of cancers in the chest area, especially during the period of breast development
- postmenopausal HRT with estrogen for several years or more
- contraceptive use
- having dense breasts
- having taken diethylstilbestrol (DES) to prevent miscarriage in the 1940s through the 1960s

Causes and symptoms

Genetic, environmental, and lifestyle factors all have roles in causing breast cancer. However, more than 70% of women with breast cancer have no known risk factors. All cancers are thought to be caused by changes (mutations) in genes that affect proteins that regulate metabolic functions, especially genes and proteins that control cell division. Genetic factors appear to be the most important cause of breast cancer. About 20–30% of women with breast cancer have a family history of the disease. About half of breast cancers in women from families with a high incidence of breast cancer have mutations affecting the BRCA1 or BRCA2 genes that normally produce proteins that protect against cancer. Various other genes that may influence the development of breast cancer have been identified, including ATM, CHEK2, p53, and PTEN.

There are usually no symptoms of early breast cancer. A hard, usually painless lump in the breast or armpit that has uneven edges may be the first symptom. Other symptoms may be a change in the size, shape, or feel of a breast or nipple, such as redness, dimpling, puckering, or nipple retraction, or a nipple discharge. A bloody discharge is most often caused by benign disease, and not all breast lumps are cancerous. Fibrocystic changes in the breast are extremely common and a leading cause of noncancerous lumps. Fibrocystic changes may be solid or fluid-filled lumps that cause **pain**, swelling, or discharge. Symptoms of male breast cancer include a breast lump and breast tenderness and pain.

Symptoms of advanced breast cancer may include the following:

- breast discomfort or pain
- armpit swelling
- skin ulcers
- weight loss
- bone loss

Diagnosis

Examination

Women are encouraged to perform regular monthly breast self-examinations to check for any lumps, pain, or other abnormalities. Professional breast exams should be performed as part of a woman's annual physical exam. The healthcare provider will feel for abnormalities in the breasts, armpits, and neck and chest area. Breast exams, along with **mammography**, can detect breast cancer early when it is most treatable. The healthcare provider will ask about any symptoms and risk factors for breast cancer.

A complete diagnostic evaluation of any significant breast abnormality is mandatory, since the signs and symptoms of benign fibrocystic breast changes can be similar to those of breast cancer. Furthermore, certain benign changes in the breast may be linked to increased risk for breast cancer. Skin dimpling or nipple retraction in the presence of an underlying breast mass on examination is a more advanced finding. Skin involvement, with swelling (**edema**) or ulceration of the skin, is a late symptom.

Tests

Women with a strong family history of breast cancer may have **genetic testing** for BRCA1 and BRCA2 mutations that put them at high risk for breast and other cancers. The tests are performed on a blood sample. Women who test positive will require more frequent breast cancer screenings beginning at a much younger age.

WWW.BOOKBAZ.IR

KEY TERMS

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Aromatase—An enzyme that converts an androgen to an estrogen; aromatase inhibitors are used to treat estrogen receptor-positive breast cancer.

Axillary nodes—The underarm lymph nodes.

Benign—Not malignant, noncancerous.

Biologic therapy—Targeted therapy; use of monoclonal antibodies to inactivate or destroy HER2-positive breast cancer cells.

Biopsy—A procedure for removing tissue for examination by a pathologist.

BRCA1 and BRCA2—BReast CAncer susceptibility genes; specific mutations in these genes greatly increase the risk of breast cancer.

Ductal carcinoma—Breast cancer that originates in the lining of the milk duct; ductal carcinoma in situ (DCIS) is ductal cancer that has not become invasive.

Estrogen receptor (ER)—A protein on the surface of cells that binds the female hormone estrogen, initiating estrogenic effects, and present on ER-positive breast cancer cells.

Human epidermal growth factor receptor 2 (HER2)—A growth factor that is overproduced in HER2-positive breast cancers.

Hormone replacement therapy (HRT)—Treatment of menopausal symptoms with the female hormones estrogen and/or progesterone.

Hormone therapy—Cancer treatment that affects the hormone balance of the body, such as blocking estrogen receptors or preventing estrogen production.

Lobular carcinoma—Breast cancer that originates in the milk glands.

Lumpectomy—Breast-conserving surgery that removes only the cancerous tumor and a limited amount of normal surrounding tissue.

Lymph nodes—Small, bean-shaped masses of tissue throughout the lymphatic system that act as filters and immune monitors, removing fluids, bacteria, and cancer cells; breast cancer cells in the lymph nodes under the arm or in the chest are a sign that the cancer has spread or might recur.

Magnetic resonance imaging (MRI)—A diagnostic technique that provides cross-sectional images of structures, such as the breasts.

Malignant—Cancerous.

Mammogram—A breast x ray.

Mastectomy—Surgical removal of part or all of the breast and possibly associated lymph nodes and muscle.

Metastasis—The spread of cancer from its initial site to another part of the body.

Monoclonal antibodies—Identical antibodies that recognize a specific type of cancer cell.

Progesterone receptor (PR)—A cell-surface protein that binds the female hormone progesterone; breast cancer cells are often PR-positive.

Selective estrogen receptor modulator (SERM)—A drug such as tamoxifen that interferes with the binding of estrogen to its receptor; used to prevent and treat breast cancer.

Sentinel node—The first lymph node to receive drainage from a primary tumor.

Staging—Classifying the extent or severity of a disease based on established criteria.

Triple-negative breast cancer—Aggressive and difficult-to-treat breast cancer in which the cells do not express estrogen and progesterone receptors and do not overexpress HER2.

Procedures

Any changes detected by breast examination should be examined immediately by mammography. All women should have periodic mammogram screenings for breast cancer beginning at age 40 and in the early 20s for women at high risk for breast cancer because of a significant family history or known BRCA gene mutations. Mammography is low-dose x-ray imaging of each breast from two different views. Mammography can detect breast cancer that is not detectable by **physical examination**. More than 90% of all breast cancers are detected by mammogram screenings. However, about 10% of breast cancers are not detected with mammography. **Magnetic resonance imaging** (MRI) may be used to evaluate a breast lump or mammogram abnormality, as well as for screening in some high-risk women. **Ultrasound** can distinguish between a solid lump and a fluid-filled cyst.

A biopsy, the removal of tissue for examination by a pathologist, is performed on any suspicious lump or abnormality. The biopsy is often guided with ultrasound. An incisional biopsy is the removal of a tissue sample. A fine-needle aspiration biopsy passes a fine-gauge needle into the lesion and suctions out cells for microscopic evaluation (**cytology**). A sample of any nipple discharge may also be examined. Fine-needle aspiration is a simple procedure performed under local **anesthesia** and reveals whether the lesion is solid or a fluid-filled cyst. If the lesion is a simple cyst, the fluid is removed. Core needle biopsies, which are also simple procedures performed under local anesthesia, remove larger amounts of tissue to preserve their architecture. If diagnosis with a needle biopsy is questionable, a complete open surgical or excisional biopsy may be performed to remove the mass.

Staging

Following a diagnosis of breast cancer, staging is performed to determine whether or how far the cancer has spread. Tests include a blood count and blood tests for liver function and the level of alkaline phosphatase, an enzyme from bone. Procedures may include the following:

- sentinel lymph node biopsy or removal to determine whether cancer has spread to the lymph node closest to the cancer
- chest x rays
- computed tomography (CT) or positron emission tomography (PET) scans
- radionuclear bone scans

In the United States, breast cancer is staged by the TNM system: tumor size or increase (T), cancer spread to the lymph nodes (N), and metastasis (M) to distant sites in the body:

- stage 0—noninvasive (in situ) cancer such as DCIS
- stage I—cancer no larger than 2 cm (0.8 in.) in diameter and no cancer cells in lymph nodes
- stage II—no tumor in the breast or tumor size less than 2 cm (0.8 in.), but breast cancer cells in lymph nodes under the arm; tumor size is 2–5 cm (0.8–2 in.) and may or may not have spread to underarm lymph nodes; or the tumor is larger than 5 cm (2 in.) but has not spread to any lymph nodes
- stage III—cancer has not spread to distant sites
- stage IIIA—tumor larger than 5 cm (2 in.) and has spread to one to three underarm lymph nodes; or tumor of any size that has spread to multiple lymph nodes, which are clumped together or attached to surrounding tissue
- stage IIIB—cancer has spread to tissues near the breast (skin or chest muscles) and possibly to lymph nodes within the breast or under the arm; or inflammatory breast cancer, an uncommon but aggressive form
- stage IIIC—tumor has spread to 10 or more underarm lymph nodes, lymph nodes above or below the collarbone or near the neck, or lymph nodes within the breast and under the arm
- stage IV—cancer has spread to distant regions, such the lungs, liver, bones, or brain

Treatment

Traditional

Treatment depends on the type and stage of the cancer, whether it is hormone-sensitive, and whether it overexpresses HER2. A combination of treatments, radiation, **lumpectomy** (removal of the breast lump) or **mastectomy** (removal of part or all of the breast and possibly nearby structures), **chemotherapy**, and/or hormone or biologic therapies, may be used in an appropriate sequence. Mammography and various tests are continued following treatment. The treatment goal for stages 0–III is to cure the cancer, that is, to destroy it and prevent it from recurring. The goal for stage IV breast cancer is to improve symptoms and extend life.

- Stage 0 and DCIS are treated by lumpectomy and radiation or mastectomy.
- Stages I and II are treated with lumpectomy plus radiation or mastectomy and lymph node removal, possibly followed by hormone therapy, chemotherapy, and/or biologic therapy.
- Stage III is treated with surgery, possibly followed by hormone therapy, chemotherapy, and/or biologic therapy.
- Stage IV may be treated with surgery, radiation, chemotherapy, and/or hormone therapy.

Historically, radical mastectomy, surgical removal of the entire breast and axillary lymph nodes, along with the muscles down to the chest wall, was the standard treatment for breast cancer. By the later twentieth century, lumpectomies and other breast-conserving treatments significantly reduced the number of radical mastectomies. A lumpectomy (or segmental mastectomy) and axillary dissection are the primary therapy for tumors less than 4 cm (1.5 in.) in size that can be removed without destroying the appearance of the breast: only the primary tumor and a rim of normal tissue are removed, and the axillary nodes are removed for staging purposes, usually through a separate incision. Subsequent **radiation therapy** reduces the risk of

WWW.BOOKBAZ.IR

recurrence in the remaining breast tissue. Mastectomies may be followed by reconstructive breast surgery, either in conjunction with the mastectomy or at a later date.

As with surgery, radiation therapy is a local treatment in which only the specific tissue is exposed to radiation. It is usually performed post-operatively after surgical **wounds** have healed. Radiation is also used for stage IV disease to reduce pain and prevent **fractures** if the cancer has metastasized to bone.

Drugs

CHEMOTHERAPY. Chemotherapy may be administered after surgery to destroy any residual cancer or undetectable metastasized cancer cells and reduce the risk of recurrence. Chemotherapy is administered either orally or by injection into a blood vessel and usually involves multiple drugs. It is given in cycles, with a recovery period followed by another course of drugs. Because chemotherapy is systemic, affecting the entire body, it can produce significant side effects, including **nausea and vomiting**, temporary hair loss, mouth or vaginal sores, **fatigue**, weakened immune system, and **infertility**.

HORMONE THERAPY. Surgically removed tumor tissue is tested to determine whether the cancer cells have receptors for estrogen and progesterone. About 70% of breast cancers, especially those in postmenopausal women, are ER-positive, and most of these are also progesterone receptor (PR)-positive. The drug tamoxifen binds to estrogen receptors on ER-positive cancer cells, thereby preventing estrogen from binding and stimulating cancer cell growth. Tamoxifen has been used for hormone receptor-positive breast cancer for more than 30 years. It is commonly prescribed for five years as an adjunct to primary treatment. Cancer that is unresponsive to tamoxifen may be treated with similar drugs such as toremifene (Fareston) or raloxifene (Evista). These drugs are known as selective estrogen receptor modulators (SERMs). Most SERMS block estrogen in some tissues and mimic estrogen in others: for example, tamoxifen blocks estrogen effects in breast tissue but has estrogenic activity in bone and the uterus. Fulvestrant (Faslodex) also binds to and blocks estrogen receptors, but it is not a SERM because it targets the receptor for destruction and has no estrogenic effects elsewhere in the body.

Aromatase inhibitors block the enzyme aromatase that is necessary for producing estrogen in the ovaries and other tissues. These drugs are used to treat both early and advanced breast cancer in postmenopausal women. Premenopausal women generally have too much aromatase to be effectively blocked by the drugs, unless they are used in conjunction with a drug that suppresses ovarian activity. Aromatase inhibitors include letrozole (Femara) and anastrozole (Arimidex), which temporarily block aromatase, and exemestane (Aromasin) that permanently blocks aromatase.

BIOLOGIC THERAPY. Biologic or targeted therapy is the use of a single type of antibody, called **monoclonal antibodies**, that react with specific receptors on cancer cells and inactivate or destroy the cells without affecting other cells. Trastuzumab (Herceptin) and lapatinib (Tykerb) target HER2-positive cancer cells that are present in 15–25% of breast cancers.

In 2013, the U.S. Food and Drug Administration (FDA) approved a type of drug called an antibody-drug conjugate that combines Herceptin with a strong toxin that kills the cancer cells more effectively. It may also reduce side effects, because the toxin remains inactive until the antibody binds to the tumor cell. In a clinical trial, the drug extended the median survival of women with advanced breast cancer by almost six months.

Alternatives

Complementary treatments are alternative therapies used alongside conventional medicine. They are often effective for moderating side effects of conventional treatments and improving quality of life. For example, **acupuncture** and **guided imagery** may be useful for treating pain and side effects of chemotherapy associated with breast cancer. Acupuncture is the placement of thin needles into the skin at targeted locations on the body known as acupoints, in order to harmonize energy flow within the body. Guided imagery involves creating a mental image of pain that the patient can adjust to be more manageable.

Many herbal remedies, including medical **marijuana** in some states, can lessen pain and chemotherapy side effects such as nausea and promote relaxation and healing. However, depending on the type and preparation, some remedies may interact with and enhance or diminish the effects of prescribed medications. Ginger (*Zingiber officinale*) is generally regarded as helpful for relieving chemotherapy-induced nausea.

Home remedies

Specific exercises for the arm, shoulder, and chest can help patients regain strength and flexibility following breast cancer surgery. About 5–7% of patients who undergo complete axillary lymph node resection develop clinically significant **lymphedema** (swelling in

the arm), which can be treated by intermittent elevation and massage.

Prognosis

Prognosis depends on the type and stage of the breast cancer; however, between 1990 and 2013, death rates from breast cancer fell by 34%. Earlier stages with little or no lymph node involvement have very high survival rates. Although the cancer can recur, tamoxifen has reduced the risk of ER-positive breast cancer recurrence by about 50%.

Prevention

Breast cancer may not preventable, but lifestyle choices can eliminate some risk factors as well as promote general health and well-being. Some studies suggest that women who consume plenty of fruits, vegetables, and legumes, especially red, yellow, and orange produce such as carrots, spinach, kale, sweet potatoes, winter squash, and red peppers, and only small amounts of red meat, processed carbohydrates, and salt may lower their risk of ER-negative breast cancer, which accounts for approximately 25% of breast cancers. Researchers also found that women who ate raw or lightly cooked cabbage and sauerkraut at least three times per week were 72% less likely to develop breast cancer. Higher **vitamin D** levels have been associated with a lower risk for breast cancer. According to the American Cancer Society, two to five alcoholic drinks daily increases the risk of breast cancer by 50%. Thus, healthy choices include the following:

- maintaining a healthy weight
- consuming more fruits and vegetables
- replacing refined grain products with whole grains
- limiting processed and red meats
- limiting alcohol to one drink daily and abstaining altogether if at high risk for breast cancer

Monthly breast self-exams and periodic screening mammograms significantly aid early detection and treatment, which greatly increases chances of survival. The U.S. Preventive Services Task Force recommends that women should have screening mammograms every two years beginning at age 50 and continuing until age 74; women with significant risk factors should begin mammograms at an earlier age and have them more frequently. However, the American Cancer Society calls for annual mammograms beginning at age 40 and continuing as long as a woman is in good health. The National Cancer Institute recommends mammograms every one to two years beginning at age 40. Women at high risk for breast cancer should initiate mammograms at an early age and have them more frequently. They should also have MRIs periodically.

Some women at very high risk for breast cancer because of BRCA mutations, a strong family history of breast cancer, or removal of one breast because of cancer, choose preventive (prophylactic) mastectomy, the removal of healthy breasts. Total double mastectomy reduces, but does not eliminate, the risk of breast cancer. Tamoxifen, raloxifene, or exemestane have been recommended for breast cancer prevention in postmenopausal women. Tamoxifen is approved for breast cancer prevention in high-risk women aged 35 and older. Although these drugs can lower the risk of breast cancer, they can have adverse effects such as **blood clots** and strokes, and so they are only recommended as preventives for women at increased risk because of a family or personal history of breast cancer or certain other conditions. In 2013, the U.S. Preventive Services Task Force estimated that prophylactic tamoxifen or raloxifene over a period of five years would prevent seven to nine of the expected 23.5 cases of invasive breast cancer among each 1,000 women at increased risk; however, four to seven of every 1,000 women taking one of the drugs would develop blood clots, and there would be four to seven additional cases of uterine cancer per 1,000 women taking tamoxifen over the same period. Thus, a woman would likely benefit from the drugs if her five-year risk of breast cancer was at least 3%.

Breast enlargement *see* **Breast implants**

Breast implants

Definition

Breast implantation is a surgical procedure for enlarging or augmenting the breast. Implants are breast-shaped pouches that are saccular in shape, made of a silicone outer shell, and filled with silicone gel or saline (salt water).

Purpose

Breast implantation is usually performed to make normal breasts larger for cosmetic purposes. Sometimes a woman having **breast reconstruction** after a

A silicone breast implant. *(AP Images.)*

KEY TERMS

Breast augmentation—A surgery to increase the size of the breasts.

Contracture—Tissue change that is characterized by shortening of length, usually producing wrinkles or areas of thickening.

Transsexual—Person desiring to acquire the external appearance of a member of the opposite gender.

mastectomy will need the remaining breast enlarged to make the breasts more symmetrical. Breasts that are very unequal in size due to **trauma** or congenital deformity may also be equalized with an enlargement procedure.

Male-to-female transsexuals may use breast implantation to achieve the physical appearance of a female.

Demographics

Breast enlargement is the second most common cosmetic surgical procedure practiced on women in the United States. It increased by approximately 350% between 1992 and 2006. According to the American Society of Plastic Surgeons, almost 150,000 breast augmentation procedures are performed each year.

Presently, more than two million, or approximately 8%, of women in the United States have breast implants. The majority of breast implant recipients are Caucasian women (95%), followed by African American women (4%). The remaining women that have breast implants are Asian (0.5%) and other non-specified races (0.5%).

Description

Breast augmentation is normally performed by a surgeon with advanced training in plastic and reconstructive procedures. It is typically performed as an outpatient procedure.

Cosmetic breast enlargement or augmentation may be done under local or general **anesthesia**, depending on patient and physician preference. The incision is typically made through the armpit (axilla), along the fold line under the breast, or around the areola (the darkened area around the nipple); these techniques create the most inconspicuous **scars**. The implant is placed in one of two locations: between the breast tissue and underlying chest muscle, or under the chest muscle. The operation takes approximately one to two hours. The cost of a cosmetic procedure is rarely covered by insurance; however, if enlargement is part of breast reconstruction after a mastectomy, health plans may pay for some or all of it. The surgeon's fee ranges from $3,500 to $5,000, and up. The procedure may also be called breast augmentation or augmentation mammoplasty.

Diagnosis

The diagnosis for breast reconstruction is almost always visual. The underlying medical reasons include equalizing otherwise normal breasts that are markedly different in size, replacing all or part of breast tissue that has been removed during the course of cancer treatment, or replacing breast mass that has been lost due to injury. Underlying cosmetic reasons include personal preference for larger breasts among genetic females or the creation of breasts in male-to-female transsexuals.

Preparation

Before any surgery is performed, the woman should have a clear understanding of what her new breasts will look like. She and her physician should agree about the desired final result. Many surgeons find it helpful to have the patient review before and after pictures of other patients to clarify expectations. Computer modeling is often used to assess expected results.

A person who is in poor health or has a severe or chronic disease is not a good candidate for this procedure.

Aftercare

Many normal activities such as driving may be restricted for up to one week. Sutures are usually removed in seven to ten days. Typically, a woman can resume all routines, including vigorous **exercise**, in about three weeks. The scars will be red for approximately one month, but will fade to their final appearance within one to two years.

Risks

Risks associated with this procedure are similar to those of any surgical procedure. These risks include bleeding, infection, reaction to anesthesia, or unexpected scarring. A breast enlargement may also result in decreased sensation in the breast or interference with breastfeeding. Implants can make it more difficult to read and interpret mammograms, possibly delaying **breast cancer** detection. Also, the implant

WWW.BOOKBAZ.IR

itself can rupture and leak, or become displaced. A thick scar that normally forms around the implant, called a capsule, can become very hard. This is called capsular contracture, and may result in **pain** and possible altered appearance of the breast. The chances that these problems will occur increase with the age of the implant.

There has been intermittent publicity about possible health risks associated with breast implants. Most concerns have focused on silicone gel-filled implants that leaked or ruptured. In 1992, the U.S. Food and Drug Administration (FDA) restricted the use of this type of implant and ordered further studies. The FDA lifted the ban on silicone implants in 2007, although saline-filled implants are still more commonly used for cosmetic breast surgery. Studies have shown no evidence of long-term health risks from intact silicone implants; however, research on possible links between these implants and autoimmune or connective tissue diseases is continuing.

Results

Breasts of expected size and appearance are the normal results of this surgery. Normal scar formation should be expected. With any silicone prosthesis, a capsule usually forms around it. In some instances, a mild form of capsular contraction ensues. Mild ridges that can be felt under the skin categorize this condition. The capsule contracts, which occurs occasionally, and can result in a hardening of the breast. There is no way to predict who will excessively scar.

Morbidity and mortality rates

In addition to scarring, other risks include infection, excessive bleeding, problems associated with anesthesia, rupturing of the implant, and leakage. There have been approximately 120,000 reports of ruptured silicone implants. Approximately 50,000 reports of breakage have been received for saline implants.

Deaths associated with breast augmentation are extremely rare. Most postsurgical mortality has been attributed to anesthesia errors or overdoses of pain medications.

Alternatives

Alternatives to breast implant surgery include using external breast forms that fit into brassiere cups or are attached to the skin of the chest. Creams that allege to increase breast size usually produce no noticeable results. The use of creams containing hormones can lead to long-term hormonal imbalance. Reputable experts do not generally recommend these preparations for breast enlargement.

Breast reconstruction

Definition

Breast reconstruction consists of a series of surgical procedures performed to recreate a breast. Reconstructions commonly begin after portions of one or both breasts are removed as a treatment for **breast cancer**. Breast reconstruction surgery may also be performed for other reasons such as **trauma** or to correct abnormalities that occur during breast development. A procedure known as augmentation mammoplasty may be performed on the unaffected breast to increase fullness or to improve the symmetry of the breasts.

Purpose

Many experts consider reconstruction to be an integral component of the therapy for breast cancer. A naturally appearing breast offers a sense of wholeness and normalcy, which can aid in the psychological recovery from breast cancer. It eliminates the need for an external prosthesis (false breast), which many women find to be physically uncomfortable as well as inconvenient.

Demographics

Breast reconstruction is the in the top five most commonly performed reconstructive plastic surgical procedures in the United States. According to the American Society of Plastic Surgeons, more than 91,000 breast reconstruction procedures were performed in 2012. Percentages of patients undergoing breast reconstructive procedures varied among different ethnicities: Caucasians made up the largest percentage with 72% of the patients, while 15.1% were African American, 10% were Hispanic, and 2.3% were Asian American.

The age groups most likely to undergo breast reconstruction are in the 40–54 year old and 55 or older age groups. Breast reconstruction involves the use of silicone implants about 69% of the time, which requires tissues expanders about 62% of the time. About 18,000 women annually undergo breast reconstruction that utilizes their own tissues form their backs or torsos.

Description

Breast reconstruction is normally performed by a surgeon with advanced training in plastic and reconstructive procedures. It is commonly, but not exclusively, performed as an outpatient procedure.

Breast reconstruction is performed in two stages, with the ultimate goal of creating a breast that looks and feels as natural as possible. It is important to remember that while a good result may closely mimic a normal breast, there will inevitably be **scars** and some loss of sensation. The reconstructed breast cannot exactly match the original.

The first step is to create a structure called a breast mound. This can be accomplished using artificial materials called **breast implants**, or by using tissues from other parts of the woman's body. The second step involves creating a balance between the newly constructed breast and the breast on the opposite side. The nipple and areolar complex (darker area around the nipple) are recreated. This is usually done several months after the mound is created to allow swelling to subside. Other procedures may be necessary, such as lifting the opposite breast (mastopexy) or making it larger or smaller to match the reconstructed breast.

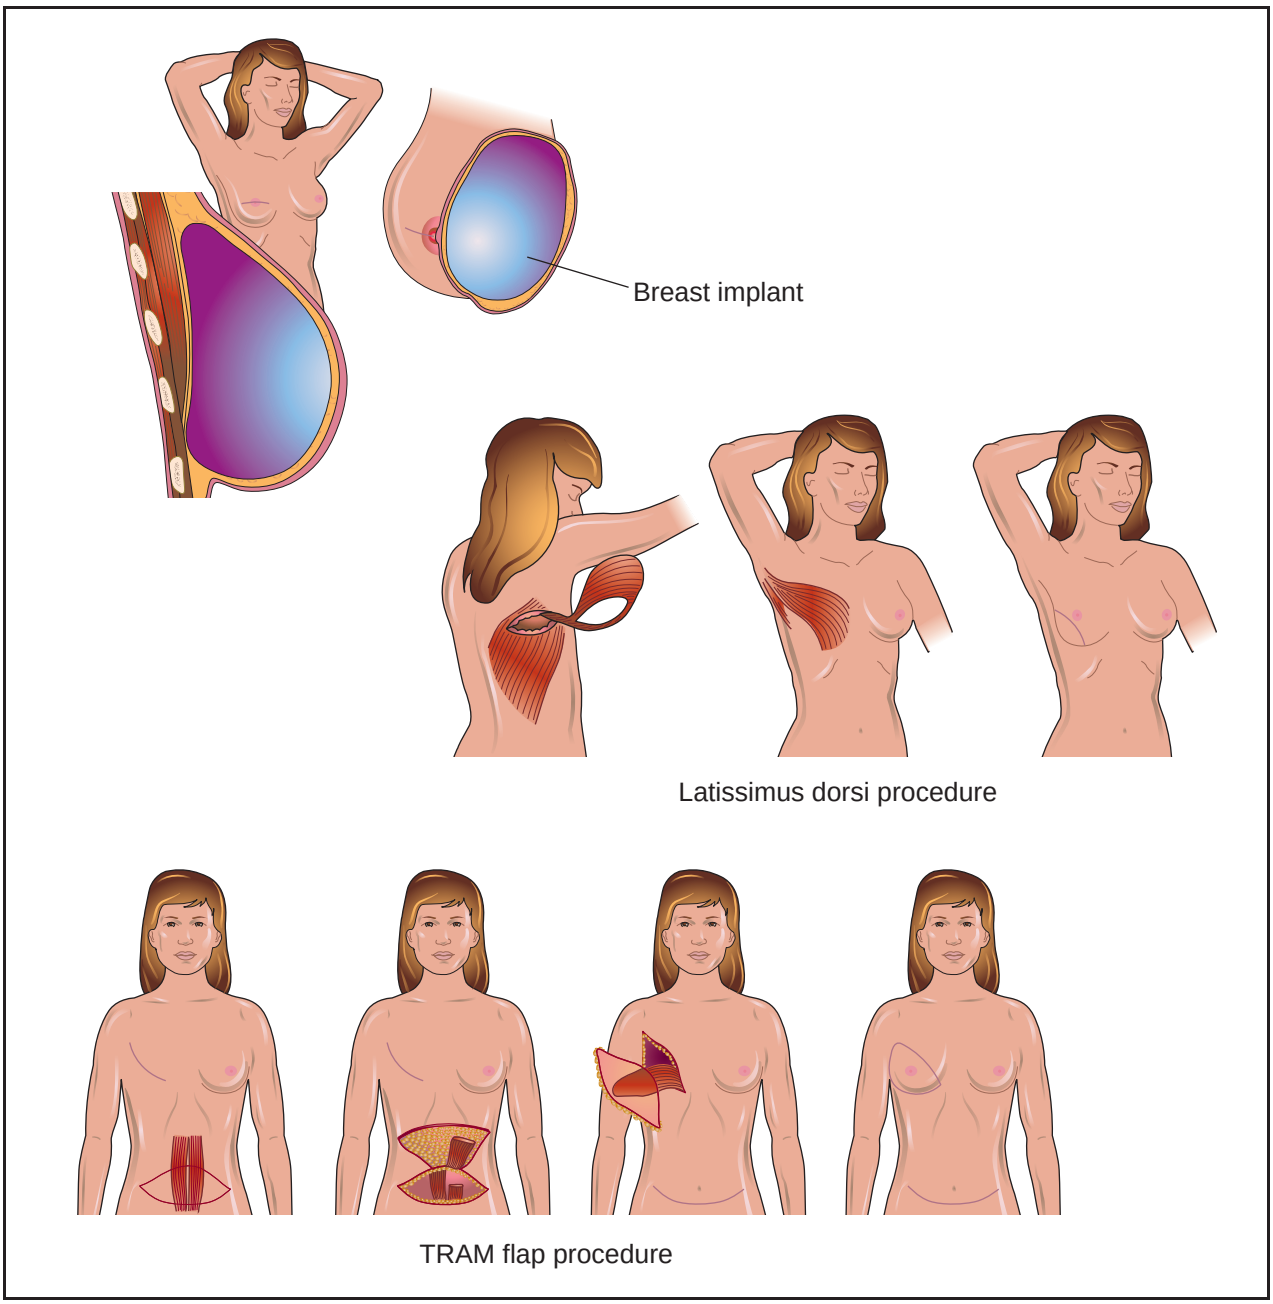
Immediate or delayed reconstruction

While immediate reconstruction (IR) is not recommended for women with breast cancer who need to undergo other, more important treatments, breast reconstruction can be done almost anytime. It can be delayed, or it can be completed during the same procedure as the **mastectomy**. There are psychological benefits to IR. The ability to return to normal activities and routines is often enhanced when reconstruction follows immediately after mastectomy. A better final appearance may result from IR. There is less skin removal, often resulting in a shorter scar. The surgeon is better able to preserve the normal boundaries of the breast, so it is easier to more closely match the opposite breast.

The cost of IR is generally lower than the cost of delayed reconstruction (DR), as there is one less operation and hospital stay. Surgeons' fees may be lower for a combined procedure than for two separate surgeries.

There are disadvantages of IR as well. The surgery itself is longer, resulting in more time under **anesthesia**. Postoperative **pain** and recovery time will be greater than for mastectomy alone.

WWW.BOOKBAZ.IR



Breast reconstruction surgery may be performed by inserting an artificial substance, or implant, to replace breast tissue. Autologous reconstruction, in which a woman's own tissues are used, includes the latissimus dorsi flap, where skin and muscle taken from the back are rotated around to the breast area, and the TRAM flap, in which abdominal fat and muscle are tunneled under the skin to the breast area. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Other authorities contend that delayed reconstruction (DR) offers different physical and psychological advantages. The initial mastectomy procedure alone takes less time and has a shorter recovery period and less pain than mastectomy and IR. The woman has more time to adjust to her diagnosis and recover from additional therapy. She is better able to review and evaluate her options and to formulate realistic goals for reconstruction. Some **reconstructive surgery** requires blood transfusions. With DR, the patient can donate her own blood ahead of time (autologous **blood donation**), and/or arrange to have family and friends donate blood for her use (directed donation).

KEY TERMS

Autologous—From the same person; an autologous breast reconstruction uses the woman's own tissues, while an autologous blood transfusion is blood removed then transfused back to the same person at a later time.

Capsular contracture—Thick scar tissue around a breast implant, which may tighten and cause discomfort and/or firmness.

Flap—A section of tissue moved from one area of the body to another.

Free flap—A section of tissue that is detached from its blood supply, moved to another part of the body, and reattached by microsurgery to a new blood supply.

Mastectomy—Removal of all or a portion of breast tissue.

Mastopexy—Surgical procedure to lift up a breast; may be used on opposite breast to achieve symmetrical appearance with a reconstructed breast.

Pedicle flap—Also called an attached flap; this is a section of tissue, with its blood supply intact, which is maneuvered to another part of the body.

The psychological **stress** of living without a breast is a disadvantage of DR. The extra procedure needed to perform DR results in higher costs. Although initial recovery is faster, an additional recuperation period is required after the delayed operation.

Type of reconstruction

There are two basic choices for breast reconstruction. The breast tissue can be replaced with an implant, or the breast is created using some of the woman's own tissues (autologous reconstruction).

ARTIFICIAL IMPLANTS. In general, implant procedures take less time and are less expensive than autologous ones. Implants are breast-shaped pouches. They are made of silicone outer shells, which may be smooth or textured. The inside contains saline (salt water). Implants made prior to 1992 were filled with silicone gel. In 1992, the U.S. Food and Drug Administration (FDA) discontinued the use of silicone as a filling material. In 2006, the FDA again allowed silicone gel for use in implants.

An implant may be a fixed-volume type, which cannot change its size. Implants that have the capacity to be filled after insertion are called tissue expanders. These may be temporary or permanent.

The initial procedure for any implant insertion uses the mastectomy incision to make a pocket of tissue, usually underneath the chest wall muscle. In DR, the mastectomy scar may be reopened and used for this purpose, or a more cosmetic incision may be made. The implant is inserted into the pocket, the skin is stretched as needed, and sutured closed.

If there is inadequate tissue to achieve the desired size or a naturally sagging breast is desired, a tissue expander is used. It resembles a partially deflated balloon, with an attached valve or port through which saline can be injected. After the initial surgical incision is healed, the woman returns to the doctor's office on a weekly or bi-weekly basis to have small amounts of saline injected. Injections can continue for about six to eight weeks, until the preferred size is obtained. In some cases, it may initially be overfilled and later partially deflated to allow for a more pliable, natural result. A temporary tissue expander is removed after several months and replaced with a permanent implant.

IR surgery using an implant takes approximately two to three hours, and usually requires up to a three-day hospital stay. Implant insertion surgery that is accomplished as part of DR takes one to two hours and can sometimes be done as an outpatient procedure. Alternatively, it may entail overnight hospitalization.

AUTOLOGOUS RECONSTRUCTION. Attached flap and free flap are two types of surgery where a woman's own tissue is used in reconstruction. An attached flap uses skin, muscle, and fat, leaving blood vessels attached to their original source of blood. The flap is maneuvered to the reconstruction site, keeping its original blood supply for nourishment; this is also known as a pedicle flap. The second kind of surgery is called a free flap, which also uses skin, muscle, and fat, but the surgeon severs the blood vessels and reattaches them to other vessels where the new breast is to be created. The surgeon uses a microscope to accomplish the delicate task of sewing blood vessels together (anastomosis). Sometimes, the term **microsurgery** is used to refer to free flap procedures. Either type of surgery may also be called a myocutaneous flap. This refers to the skin and muscle used.

The skin and muscle used in autologous reconstruction can come from one of several possible places on the body, including the abdomen (tummy tuck flap), the back (latissimus dorsi flap), or the buttocks (gluteus maximus free flap).

WWW.BOOKBAZ.IR

Finishing the reconstruction

Other procedures may be necessary to achieve the goal of symmetrical breasts. It may be necessary to make the opposite breast larger (augmentation), smaller (reduction), or higher (mastopexy). These, or any other refinements, should be completed before the creation of a nipple and areola. Tissue to form the new nipple may come from the reconstructed breast itself, the opposite breast, or a more distant donor site such as the inner thigh or behind the ear. The nipple and areolar construction is usually accomplished as an outpatient procedure. A final step, often done in the doctor's office, is tattooing the new nipple and areola to match the color of the opposite nipple and areola as closely as possible.

Insurance

Insurance coverage varies widely for breast reconstruction. Some policies will allow procedures on the affected breast, but refuse to pay for alterations to the opposite breast. Other plans may cover the cost of an external prosthesis or reconstructive surgery, but not both. The Women's Health and Cancer Rights Act of 1998 requires group health plans and health issuers to provide medical and surgical benefits with respect to mastectomy and to cover the cost of reconstructive breast surgery for women who have undergone a mastectomy.

Implants may pose additional insurance concerns. Some companies will withdraw coverage for women with implants, or add a disclaimer for future implant-related problems. Careful reading of insurance policies, including checking on the need for pre-approval and a second opinion, is strongly recommended.

Diagnosis

The diagnosis for breast reconstruction is almost always made on a visual basis. The underlying medical reasons include replacing all or part of breast tissue that has been removed during the course of cancer treatment, replacing breast mass that has been lost due to injury, or equalizing otherwise normal breasts that are markedly different in size. Underlying cosmetic reasons include personal preference for larger breasts among genetic females or the creation of breasts in male-to-female transsexuals.

Preparation

Routine preoperative preparations, such as having nothing to eat or drink the night before surgery, are needed for reconstructive procedures. Blood transfusions may be necessary for autologous reconstructive surgeries. The patient may donate her own blood and/or have family and friends donate blood for her use several weeks prior to the surgery.

Emotional preparation is also important. Breast reconstruction will not resolve a psychological problem the woman had before mastectomy, nor make an unstable relationship strong. An expectation of physical perfection is also unrealistic. A woman who cites any of these reasons for reconstruction shows that she has not been adequately informed or prepared. Complete understanding of the benefits and limitations of this surgery are necessary for a satisfactory result.

Not all women are good candidates for breast reconstruction. Overall poor physical health or specific problems such as cigarette **smoking**, **obesity**, high blood pressure, or diabetes will increase the chance of complications. A difficult or prolonged recovery period or failure of the reconstruction may also be a result. A woman's physical ability to cope with major surgery and recuperation should also be considered.

Aftercare

The length of the hospital stay, recovery period, and frequency of visits to the doctor after surgery vary considerably with the different types of reconstruction. In general, autologous procedures require longer hospitalization and recovery times than implant procedures. For all surgical procedures, bandages and drainage tubes remain in place for at least a day. Microsurgical or free flap procedures are most closely monitored in the first day or two after surgery. The circulation to the breast may be checked as often as every hour. Complete breast reconstruction requires at least one additional surgery to create a nipple and areola. Scars may remain red and raised for a month or longer and will fade to their final appearance within one to two years. The true, final appearance of the breasts usually will not be visible for at least one year.

Risks

Some women have reported various types of autoimmune-related connective tissue disorders, which they attribute to their implants—usually involving silicone gel implants. Lawsuits have been filed against the manufacturers of these implants. In 1992, FDA issued guidelines to greatly curtail the use of silicone implants, restricting their use to women who had to replace an existing silicone gel-filled implant. The order required recipients to sign a consent form that details the potential risks of silicone gel-filled implants and become enrolled in a long-range study. Saline became the filling of choice for breast implants.

Saline-filled implants were permitted for all uses, although manufacturers were ordered to continue to collect data on possible risks.

The FDA issued "A Status Report on Breast Implant Safety" in 1995 and revised it in March 1997. It noted that studies have not shown a serious increase in the risk of recognized autoimmune diseases in women with silicone gel-filled breast implants. It also addressed concerns about other complications and emphasized the need for further study of this issue.

In 2006, the FDA once again approved silicone gel-filled implants for breast reconstruction in women of all ages and breast augmentation in women aged 22 and older. The FDA required both approved manufacturers to study 40,000 women each for 10 years to assess potential health problems.

There are a number of risks common to any surgical procedure, such as bleeding, infection, anesthesia reaction, or unexpected scarring. Hematoma (accumulation of blood at the surgical site), or seroma (collection of fluid at the surgical site) can delay healing if they are not drained. Any breast reconstruction also poses a risk of asymmetry and the possible need for an unplanned surgical revision. Persistent pain is another potential complication of all types of breast reconstruction.

Implants have some unique problems that may develop. A thick scar, called a capsule, forms around the implant as part of the body's normal reaction to a foreign substance. Capsular contracture occurs when the scar becomes firm or hardened. This may cause pain accompanied by changes in the texture or appearance of the breast. Implants can rupture and leak, deflate, or become displaced. The chances of capsular contracture or rupture increase with the age of the implant. These complications can usually be remedied with outpatient surgery to loosen the capsule and remove or replace the implant as needed. There is some evidence that using implants with textured surfaces may decrease the incidence of these problems. An implant tends to remain firm indefinitely. It will not grow larger or smaller as a woman's weight changes. Asymmetry can develop if a woman gains or loses a large amount of weight.

The autologous procedures all carry a risk of flap failure, which is a loss of blood supply to the tissue forming the new breast. If a large portion of the flap develops inadequate blood supply, another reconstructive technique may be necessary. Tummy tuck flap procedures can result in decreased muscle tone and weakness in the abdomen, or lead to an abdominal **hernia**. Arm weakness may occur after latissimus dorsi flap surgery.

Results

A normal result of breast reconstruction depends on the woman's goals and expectations. It will not be the same as the breast it replaces. In general, the reconstructed breast should be similar in size and shape to the opposite breast, but will have less sensation and be less mobile than a natural breast. A reconstruction using an implant will usually be firmer and rounder than the other breast. It may feel cooler to the touch, depending on the amount of tissue over it. Scars are unavoidable, but should be as inconspicuous as possible.

Morbidity and mortality rates

Normal scar formation should be expected. With any silicone prosthesis, a capsule usually forms around it; however, in some instances, a mild form of capsular contraction may develop. Mild ridges that can be felt under the skin categorize this condition. If the capsule contracts, as occasionally occurs, it results in a hardening of the breast. There is no way to predict who will excessively scar. Other risks include infection, excessive bleeding, problems associated with anesthesia, rupturing of the implant, and leakage. There have been a total of 120,000 reports of ruptured silicone implants. Approximately 50,000 reports of breakage were received for saline implants. Most studies have failed to link implants to serious or chronic diseases such as cancer and lupus, but questions remain over how often the implants rupture and what happens if the silicone enters the body. One of the approved manufacturers reported that its implants have a 14% likelihood of rupturing over a 10 year period. The other conducted a three year study and reported that the rupture rate after three years was negligible.

Deaths associated with breast reconstruction are extremely rare. Most postsurgical mortality has been attributed to anesthesia errors or overdoses of pain medications.

Alternatives

Alternatives to breast reconstruction surgery include using external breast forms that fit into brassiere cups or are attached to the skin of the chest. Creams that allege to increase breast size usually produce no noticeable results. The use of creams containing hormones can lead to long-term hormonal imbalances. Reputable experts do not generally recommend these preparations for breast enlargement.

Breast reduction

Definition

Breast reduction is a surgical procedure performed to decrease the size of the breasts.

Purpose

Women with very large breasts (macromastia, or mammary hyperplasia) seek breast reduction for relief of back, shoulder, and neck **pain**. They may also feel uncomfortable about their breast size and have difficulty finding clothing that will fit properly. Breast reduction may be needed after **reconstructive surgery** following the surgical removal of cancerous breast tissue (**mastectomy**), to make the breasts more symmetric.

Men who have enlarged breasts (**gynecomastia**) may also be candidates for breast reduction surgery. Excessive alcohol intake, **marijuana** use, or using anabolic **steroids** may cause gynecomastia. Surgery is not recommended for men who continue to use these products.

KEY TERMS

Gynecomastia—Overly developed or enlarged breasts in a male.

Macromastia—Excessive size of the breasts.

Mammary hyperplasia—Increased size of the breast.

Demographics

According to the American Society of Plastic Surgeons, more than 112,000 women and 22,000 males underwent breast reduction surgery in 2012.

Description

Breast reduction surgery is normally performed by a surgeon with advanced training in plastic and reconstructive procedures. It is commonly, but not exclusively, performed as an inpatient procedure in a hospital.

Breast reduction is also called reduction mammoplasty. It is most often performed in a hospital, under general anesthetic. Studies have suggested that an outpatient procedure, using local anesthetic and mild **sedation**, may be appropriate for some persons. The operation requires approximately two to four hours. The most commonly made incision encircles the areola (darkened area around the nipple) and extends downward and around the underside of the breast. This produces the least conspicuous scar. Excess tissue, fat, and skin are removed, and the nipple and areola are repositioned. In certain cases, **liposuction** (fat suctioning) is used to remove extra fat from the armpit area. A hospital stay of up to three days may be needed for recovery.

Breast reduction surgery for males with gynecomastia is similar to that described for females.

If deemed medically necessary, breast reduction is covered by some insurance plans; however, a specified amount of breast tissue may need to be removed in order to qualify for coverage.

Preparation

Consultation between surgeon and patient is important to ensure that there is understanding and agreement with the expected final results of the procedure. Measurements and photographs may be taken. Many doctors also recommend a mammogram before the operation to ensure that there is no cancer.

Aftercare

After the surgery, an elastic bandage or special supportive bra is placed over gauze bandages and drainage tubes. The bandages and tubes are removed in a day or two. The bra is worn around the clock for several weeks. Stitches are removed one to three weeks after the operation. Normal activities, including sexual relations, may be restricted for several weeks. **Scars** will typically remain red and perhaps raised for up to several months, but will gradually fade and become less noticeable. It may take up to a year before the breasts achieve their final position and size.

Risks

Breast reduction surgery is not recommended for women whose breasts are not fully developed or who plan to breast-feed.

Risks common to any operation include bleeding, infection, **anesthesia** reactions, or unexpected scarring. Breast reduction may result in decreased feeling in the breasts or nipples and/or impaired ability to breast-feed. When healing is complete, the breasts may be slightly uneven, or the nipples may be asymmetric. This is consistent with normal breast tissue.

Results

Smaller breast size should be achieved and, with that, any previously existing pain and discomfort should be alleviated. Self-esteem should be improved for both females and males opting to have breast reduction surgery.

Morbidity and mortality rates

Deaths associated with breast reduction surgery are extremely rare. Most postsurgical mortality has been attributed to anesthesia errors, overdoses of pain medications, or postoperative infections.

In very rare cases, the skin of the breast or nipple does not heal properly and additional surgery is necessary to graft skin. Approximately 10% of women experience some loss of sensation in their nipples.

Permanent scars are left after breast reduction surgery. At first, the scars usually appear red and raised but will become less obvious over time. Women who smoke often experience more prominent scars. This is because **smoking** interferes with the healing process.

WWW.BOOKBAZ.IR

Alternatives

There are no alternatives to surgery as a way to reduce breast tissue, although significant weight loss can decrease the size of the breast.

Breast self-examination

Definition

A breast self-examination (BSE) is an inspection by a woman of her breasts to detect **breast cancer**.

Purpose

A BSE is one of three tests the American Cancer Society recommends to help detect breast cancer in its earliest stages. By regularly examining her own breasts, a woman is more likely to find any changes that may have occurred. The best time to perform a BSE is about a week after a woman's period ends, when her breasts are not tender or swollen. If her periods are not regular, a BSE should be completed on the same day every month. A BSE should also be regularly completed by women who are pregnant, **breastfeeding**, or have **breast implants**. By combining a BSE with a **mammography** and clinical breast examination, a woman is offered the best opportunity for reducing chances of death from breast cancer through early detection. Close to 90% of breast cancers are found through a BSE. The American Cancer Society recommends that beginning at the age of 20, women complete a BSE each month by feeling for lumps or anything suspicious, as well as looking at their breasts carefully in a mirror for any changes in contour, swelling, dimpling, puckering of the skin, or changes in the nipple.

Description

To complete a monthly BSE:

- When lying down, place a pillow under the right shoulder and position the right arm behind the head. Using the finger pads of the three middle fingers on the left hand, check the entire breast area. Use small circles and follow an up-and-down pattern while pressing

firmly enough to know how the breast feels from month to month. This exam should then be repeated on the left breast using the finger pads of the right hand with the pillow under the left shoulder.

- When standing before a mirror, any changes in the shape or look of the breasts should be checked. In order to look for any skin or nipple changes such as dimpling or nipple discharge, the arms should first be placed at the sides and then overhead. Hands are then placed firmly on hips to flex chest muscles, and then the body should be bent forward.
- When taking a shower, the right arm should be raised. By using soapy hands and flat fingers the right breast and outer part of the breast can be examined. The same small circles and up-and-down pattern used when lying down should be used in an upright position. Repeat on the left breast.

Preparation

Before beginning a monthly BSE, a woman's breasts should be completely exposed.

Results

Each woman's breasts have their own normal look and feel. By completing a BSE each month, a woman can determine what is normal for her and check for changes that may arise. A regular pattern of lumpiness in the breasts is normal.

Abnormal results

If any changes are noticed during a monthly BSE, such as a new, hard lump in the breast or underarms, a doctor should examine the area immediately. Other trouble signs that should not be ignored include:

- change in breast size or shape
- dimpling or puckering of the skin
- redness, swelling, or warmth that does not go away
- a pain in one area that does not vary with a woman's monthly cycle
- a nipple that pulls in
- discharge from the nipple that begins suddenly and appears only in one breast
- one nipple that has an itchy, sore, or scaling area

Breast sonogram *see* **Breast ultrasound**

Breast ultrasound

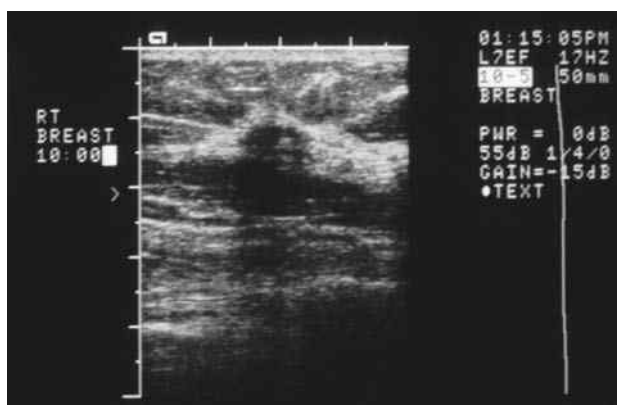
Definition

Breast **ultrasound** (or sonography) is an imaging technique for diagnosing breast disease, such as cancer. It uses harmless, high frequency sound waves to form an image (sonogram). The sound waves pass through the breast and bounce back or echo from various tissues to form a picture of the internal structures. It is not invasive and involves no radiation.

Purpose

Breast ultrasound may be used in several ways. The most common application is to investigate a specific area of the breast where a problem is suspected. A palpable lump and/or a lump or density discovered by x-ray imaging (mammogram) can be further evaluated by ultrasound. It is especially helpful in distinguishing between a fluid-filled cyst and a solid mass. It also can identify small lesions that are too tiny to be felt.

Breast ultrasound is often the first study performed to evaluate masses in women under 35 whose



A breast ultrasound image. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

KEY TERMS

Cyst—A thin-walled, fluid-filled benign structure in the breast.

Ductal carcinoma—A type of cancer that accounts for as much as 80% of breast cancers. These tumors feel bigger than they look on ultrasound or mammogram.

Fibroadenoma—A benign breast growth made up of fibrous tissue. It is the most common mass in women under 35 years of age and is found in both breasts in 3% of cases.

Infiltrating lobular carcinoma—A type of cancer that accounts for 8% to 10% of breast cancers. In breasts that are especially dense, ultrasound can be useful in identifying these masses.

Microcalcifications—Tiny flecks that are too small to be felt. They are important markers of cancer that show up on ultrasound and mammogram.

Mucinous (colloid) carcinoma—A type of cancer that accounts for 1% to 2% of breast cancers. Resembles medullary carcinoma in ultrasound and mammogram, but usually affects older women.

Nonpalpable—Cannot be felt by hand. In cancer, growths that are nonpalpable are too small to be felt but may be seen on ultrasound or mammogram.

Papillary carcinoma—A type of breast cancer that primarily occurs in older women. On ultrasound, this type of tumor may look like a solid or complex mass, or it may show up as solid tissue protruding into a cyst.

Tubular carcinoma—A type of cancer that accounts for approximately 1% to 2% of breast cancers; can appear small on ultrasound or mammogram.

mammograms can be difficult to interpret due to the density of their breast tissue. In 2003, a new study found that ultrasound was more accurate than **mammography** at diagnosing **breast cancer** in women under age 45. However, mammography still works as a screening tool, with breast ultrasound as the follow-up examination. Another study in that year found that combining ultrasound with **magnetic resonance imaging** (MRI) direction greatly improved diagnostic decisions about breast cancer lesions. The lesions detected by MRI could also be localized using ultrasound needle guidance for follow-up biopsy.

The lack of radiation used with ultrasound makes it ideal for studying breast abnormalities in women who are pregnant. Assessing **breast implants** for leakage or rupture is another use for ultrasound. Breast inflammation, where pockets of infection or abscesses may form, can be diagnosed and monitored by ultrasound.

Thickened and swollen breast skin may be a sign of inflammatory breast cancer. Ultrasound can sometimes identify a cancerous growth within the breast causing the thickened skin. These cases are usually followed by a core biopsy guided by ultrasound.

Breast ultrasound is employed to observe and guide a needle for several interventional procedures. These include cyst aspiration, fine needle aspiration, large core needle biopsy (as a first step in determining treatment for a lesion that is likely to be cancerous), and needle localization in surgical **breast biopsy**. Biopsies guided by ultrasound have distinct advantages. Patients usually find that the procedure is less traumatic and more comfortable than surgical biopsies. Ultrasound is known for its accuracy in determining how far a cancerous growth extends into the surrounding tissue in lesions that cannot be felt. Biopsies guided by ultrasound are generally less costly than surgical biopsies. Additionally, if the abnormality that requires biopsy can be seen on both a mammogram and ultrasound, an ultrasound-guided biopsy is often more comfortable for the patient as no compression is necessary.

Description

Ultrasound can be done in a doctor's office or another outpatient setting, such as a hospital or imaging center.

The patient removes her clothing from the waist up and puts on a hospital gown, open in the front. She lies on her back or side on an examining table. A gel that enhances sound transmission is spread over the area to be examined. The technologist then places a transducer, an instrument about the size of an electric shaver, against the skin. The images from reflected sound waves appear on a monitor screen.

A physician called a radiologist interprets the images obtained from ultrasound imaging. In 2003, it was reported that new computer-aided diagnosis (CAD) technology that had recently been widely added to mammography may help improve ultrasound as well. The CAD system uses computer algorithms applied to a three-dimensional ultrasound image to assign scores to

mass characteristics. Though the technology will not replace human observation and judgment, it may soon be added to support the radiologist's interpretation.

A good ultrasound study is difficult to obtain if the patient is unable to remain quietly in one position. **Obesity** may hinder clear viewing of internal structures, and the accuracy of an ultrasound study is highly dependent on the skill of the person performing the examination. The images recorded vary with the angle and pressure of the transducer and the equipment settings. The examination may take from 30 to 45 minutes. Most insurance plans cover the cost of an ultrasound examination.

Results

An ultrasound examination may reveal either normal tissue or a benign condition such as a cyst. Ultrasound can confidently diagnose a benign structure that has certain characteristics of a simple cyst. In the case of a simple cyst with no symptoms, additional treatment beyond continued observation is usually not needed.

Abnormal results

A potentially malignant mass can be identified by breast ultrasound. Abnormal results fall into the following categories: benign fibrous nodule, complex cyst, suspicious lesion, and lesion highly suggestive of cancer. In cases where ultrasound shows the presence of a complex cyst or fibrous nodule, a biopsy is justified because 10% to 15% of these growths are malignant. Lesions falling into the last two categories (suspicious or highly suggestive of cancer) have a higher chance of being cancerous and should be investigated further, either by biopsy or surgery.

Breast cancers such as the following may be identified on ultrasound: ductal carcinoma, infiltrating lobular carcinoma, medullary carcinoma, mucinous (colloid) carcinoma, tubular carcinoma, and papillary carcinoma. On ultrasound, the shape of a lesion and the type of edges it has can sometimes indicate if it is benign or cancerous, but there are exceptions. For example, benign fibroadenomas are usually oval, and some cancers can be similarly shaped. Cancerous tumors usually have jagged edges, but some benign growths can have these edges as well. Ultrasound is not a definitive test. Tissue diagnosis is often required.

Breastfeeding

Definition

Breastfeeding is the practice of feeding an infant milk through the mother's breast. According to La Leche League International (LLLI), human milk is "a living fluid that protects babies from disease and actively contributes to the development of every system in baby's body." Breastfeeding stimulates the immune systems of babies and helps to protect against **diarrhea** and infection.

Purpose

The purpose of breastfeeding is to provide healthy **nutrition** for a newborn infant at low cost.

Description

The mother's body prepares for breastfeeding while she is pregnant. The fatty tissue of the breast is replaced by glandular tissue that is necessary to produce milk. When baby suckles the breast the hormone oxytocin is released. This causes the muscle cells of the breast to squeeze milk from the milk ducts to the nipple.

History

Historically mammals have breastfed their babies. During ancient times mothers breastfed their babies for 12–18 months or until the mother's menstrual cycle returned.

For thousands of years breastfeeding was the only source of nutrition for the first part of a human baby's life. Before the invention of infant formula, few alternatives were available. If a mother could not breastfeed, a wet nurse was found or the baby was fed animal milk or "pap," a mixture of flour, rice, and water. In

Breastfeeding and medication interactions

Drug name	Use or condition treated
Safe to take in prescribed or standard doses:	
Acetaminophen (e.g., Tylenol)	Pain relief
Antacids (e.g., Maalox, Tums)	Heartburn, upset stomach
Caffeine	Stimulant
Clotrimazole (Lotrimin, Mycelex)	Antifungal
Decongestant nasal sprays (e.g., Afrin)	Nasal congestion
Fexofenadine (Allegra)	Antihistamine
Ibuprofen (e.g., Advil, Motrin)	Pain relief
Inhalers, bronchodilators, and corticosteroids	Asthma
Insulin	Diabetes
Loratadine (Claritin)	Antihistamine
Metoprolol (Lopressor, Toprol)	Hypertension
Penicillins	Bacterial infection
Propranolol (Inderal)	Hypertension
Warfarin (Coumadin)	Anticoagulant
Not safe to take in any dose:	
Amantadine	Influenza or Parkinson's disease
Antilipemics (excluding resins) or lipid-lowering drugs	High cholesterol
Antineoplastic agents	Cancer
Aspirin (large doses)	Arthritis
Clozapine	Schizophrenia
Salicylates, large doses	Arthritis

(Table by PreMediaGlobal. © Cengage Learning®.)

the early 1900s, most babies in America were still breastfed, and over half of them were breastfed for one year or longer. However, as more women entered the workforce and supplemental methods of feeding were introduced, breastfeeding rates in America decreased. According to a survey from Ross Labs, by 1971 only 24.7% of American babies were breastfed at birth, and of these babies, only 5.4% of them were still breastfed at 6 months. Beginning in the mid 1980s, breastfeeding began to be strongly encouraged in the United States. Breast milk is today considered the best nutrition for an infant, although infants can still grow and thrive on infant formula.

Demographics

In 1982, the United States experienced resurgence in breastfeeding and rates have continued to increase. The National Immunization Survey conducted by the Centers for Disease Control and Prevention (CDC) in 2005 revealed that 72% of American babies were breastfed at birth and 39% were still breastfed at 6 months.

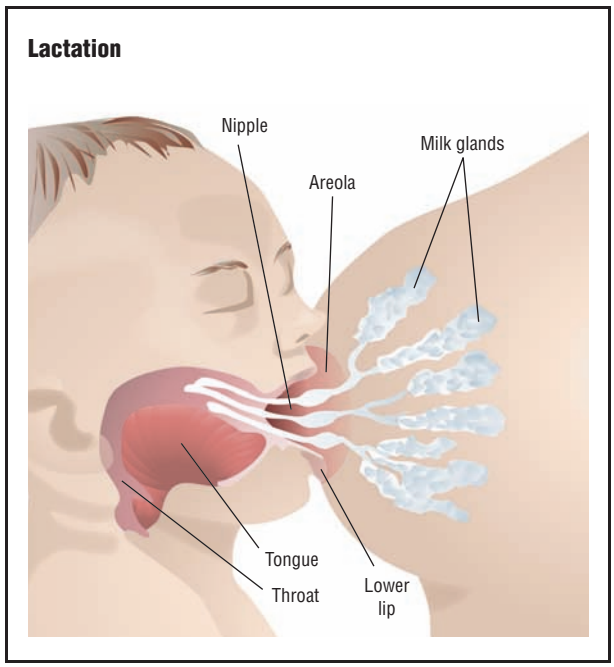
The developing world has experienced a decline in breastfeeding rates as well due to urbanization, social change, and the promotion of formula. Mothers who choose to feed their babies formula often encounter unsafe hygienic conditions in which to prepare the bottles, or they cannot afford to purchase the fuel needed to heat the water to sterilize the bottle and preparation equipment. Two of the major causes of infant mortality in developing countries are diarrhea and acute respiratory infections. Both are conditions that breastfeeding can protect against.

The World Health Organization (WHO) and the United Nations Children's Fund (UNICEF) are working together to bring about a change in the global breastfeeding culture. In 2002, they developed "The Global Strategy for Infant and Young Child Feeding," which recommends that all babies are exclusively breastfed for the first 6 months of life with continued breastfeeding up to 2 years or beyond. Exclusive breastfeeding means that breast milk is the child's only source of nutrition for the first 6 months of life and that no other solids or liquids, such as formula or water, are introduced at this time, with the exception of liquid **vitamins** or medicines. Despite this recommendation, only one-third of all babies in the developing world were exclusively breastfed for 6 months in 2004. The highest rates of exclusive breastfeeding were in the East Asia/Pacific region (43%) and the lowest rates were in the Western/Central Africa region (20%).

Composition of breast milk

Breast milk is the perfect food for an infant. It contains all the nutrients a baby needs to grow and stay healthy, such as:

- Fats. Breast milk contains omega-3 fatty acids essential for the growth and development of the brain and nerve tissue. The amount of fat a baby receives depends on the length of the feeding. The milk at the beginning of the feeding is called the foremilk. It is the low-fat milk.



When an infant is properly latched onto the breast, the baby's nose touches (or nearly touches) the breast. The baby takes the entire areola into the mouth, facilitating the intake of milk far back into the throat. *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

The hindmilk that comes at the end of the feeding contains higher concentrations of fat. Therefore, the longer the baby nurses the higher the fat content.

- Proteins. The whey proteins found in breast milk are easier to digest than formula. Taurine, an amino acid that is important in the development of brain tissue, is found in breast milk but not in cow's milk.
- Sugars. Breast milk contains lactose, a milk sugar that provides energy. Breast milk contains 20%–30% more lactose than cow's milk.
- Vitamins and minerals. Breast milk provides the most balanced source of vitamins and minerals for an infant.
- Immune system boosters. White blood cells and immunoglobulins are responsible for fighting and destroying infection.

The content of breast milk varies from feeding to feeding, at different times of day, and as the baby grows.

Benefits

Benefits for baby

There are many benefits for the breastfeeding baby, including:

- Increased immunity. Breast milk contains antibodies that are relayed by the mother and help to protect the baby from bacteria and viruses. These immunoboosters are not found in formula.
- Lower incidence of ear infections and respiratory infections.
- Potentially higher intelligence. Several studies have found higher levels of brain-boosting Docosahexaenoic acid (DHA) in the blood levels of breastfed babies than in formula-fed babies.
- Improved digestion and less constipation.
- Decreased risk of diarrhea, pneumonia, urinary tract infections, and certain types of spinal meningitis.
- Decrease in food allergies and eczema.
- More normal weight gain. Breastfed babies are less likely to be overweight than formula-fed babies.
- Reduced risk of type 1 (juvenile) and type 2 (adult onset) diabetes, celiac disease, cancer, rheumatoid arthritis, multiple sclerosis, liver disease, and acute appendicitis.
- Lower risk of sudden infant death syndrome (SIDS).
- Reduced risk of breast cancer (in daughters who have been nursed).
- Better development of jaw and facial structure
- Strong bonding between mother and child.

Benefits for mother

Breastfeeding women also enjoy many benefits:

- Reduced risk of breast, ovarian, and uterine cancers.
- Natural contraceptive. Many women who breastfeed exclusively for six months experience a delay of fertility.
- Faster postpartum recovery. Breastfeeding uses up extra calories so it is easier for moms to lose their pregnancy weight. Nursing also helps the uterus shrink back to its normal size faster.
- Relaxation. When a mother is breastfeeding her body produces oxytocin, a hormone that induces a calm, content feeling.
- Protection from osteoporosis.
- Savings in time and money. Breast milk is cheaper than formula and the mother does not have to spend time preparing bottles.
- Better stewardship of the environment, as there are no bottles to wash or cans to dispose of.

Maternal nutrition

The ideal diet of a breastfeeding woman is comprised of healthy and nutritious foods from the five basic food groups. Foods high in carbohydrate such as pastas, grains, and fruits should make up about half of the daily food intake. Healthy fats, such as fatty fish

KEY TERMS

Celiac disease—A condition in children and adults in which the body is unable to tolerate wheat protein (gluten).

Eczema—A disease in which the skin becomes dry, red, itchy, and thickened.

Foremilk—Thin watery milk found at the beginning of breastfeeding.

Galactosemia—A rare genetic disorder in which an infant cannot metabolize the sugar in breast milk and therefore cannot breastfeed.

Immunoglobulin (Ig)—A substance made by B cells that neutralizes specific disease–causing substances and organisms. Also called "antibody." Immunoglobulins are divided into five classes: IgA, IgD, IgE, IgG, and IgM.

Lactose—A sugar found in milk that provides energy.

Omega-3 fatty acids—A class of fatty acids that lowers the level of cholesterol in the blood. Omega-3 fatty acids are also essential for the growth and development of the brain and nerve tissue.

Osteoporosis—A condition found in older individuals in which bones decrease in density and become fragile and more likely to break. It can be caused by lack of vitamin D and/or calcium in the diet.

Oxytocin—A hormone that stimulates contractions during child labor and the production of breast milk.

Taurine—An amino acid that is important in the development of brain tissue. Taurine is a key component of bile that is needed to digest fats.

Type 1 diabetes—A chronic immune system disorder in which the pancreas does not produce sufficient amounts of insulin, a hormone that enables cells to use glucose for energy. Also called juvenile diabetes, it must be treated with insulin injections.

Type 2 diabetes—Formerly called adult-onset diabetes. In this form of diabetes, the pancreas either does not make enough insulin or cells become insulin resistant and do not use insulin efficiently.

and avocados, should be 30%, and proteins should equal 15%–20%. Breastfeeding women should make sure to eat foods that contain a lot of **calcium**, such as dairy products, broccoli, and beans, and make sure they eat plenty of iron-rich foods like lean red meat, fish, and poultry.

In order to compensate for the energy they expend breastfeeding their babies, breastfeeding women should add 300–500 extra nutritious calories to their diet each day and drink extra fluids. Breastfeeding mothers should also continue to take a prenatal vitamin.

Precautions

Almost every substance that a breastfeeding mother puts into her body has the potential to pass to her baby through her breast milk. This includes food, medicine, alcohol, and cigarettes.

- Foods: Foods such as dairy products, caffeine, grains and nuts, gassy foods, and spicy foods may cause the baby to fuss if the food upsets the baby's stomach. If this occurs, the mother should eliminate the suspect food from her diet for 10–14 days to see if the trouble stops.
- Medications: Any medication taken while breastfeeding should be approved by a doctor.
- Birth control pills: The high estrogen type of birth control pills may decrease a breastfeeding mother's milk supply and are not recommended. A progestin-only pill such as the "mini-pill" is the least likely to cause milk supply issues.
- Alcohol: Infants have a hard time detoxifying from the alcohol that passes through their mother's breast milk to them. It is recommended to limit alcohol consumption while breastfeeding.
- Cigarettes: Cigarettes contain toxins that can pass through to the baby and are not recommended for breastfeeding women.

When breastfeeding is not an option

Although breastfeeding is the optimal way to feed an infant, sometimes it is not possible or feasible. A small percentage of women have conditions that prevent breast milk production, such as insufficient development of milk production glands, and cannot breastfeed. Women with HIV infection are advised against breastfeeding, as the virus may be passed to their babies. Women who are newly diagnosed with infectious **tuberculosis** should not breastfeed unless they are on medication. Other health conditions may require that the woman take medication that prevents them from breastfeeding. Babies with **galactosemia**, a

rare genetic disorder that prevents them from metabolizing the sugar in breast milk, cannot breastfeed.

Breastfeeding problems

Definition

Breastfeeding problems are a variety of physical, behavioral, and emotional difficulties with nursing an infant.

Description

Breastfeeding, or nursing, is the practice of nourishing an infant with milk from the human breast. Full-term babies have a natural suckling instinct, and breastfeeding comes naturally to most as soon as they leave the womb. After delivery, levels of prolactin, the hormone that triggers milk product, begin to rise in the body. At first, babies feed on a nutrient-rich substance known as colostrum, which is produced by the breast before regular milk production begins. New mothers will experience engorgement in the days following the birth of their babies when breast milk "comes in" and engorges the breasts. After this time, regular feedings and proper breastfeeding techniques usually ensure a healthy milk supply for most babies until it is time to wean. However, breastfeeding can be a complex process and sometimes there is a problem with the infant's suckling technique, the mother's milk supply, or other factors.

Causes and symptoms

Inadequate weight gain and a **failure to thrive** in nursing infants is the most obvious sign that there is a breastfeeding problem.

Many factors may interfere with successful breastfeeding. These include:

- Milk supply problems. A variety of factors can cause an inadequate supply in new mothers. Milk production is largely a supply and demand process. If the baby does not nurse frequently enough or eat enough at each feeding, milk production will adjust itself and decrease accordingly.
- Latching problems. Some babies, particularly preterm infants, have difficulty suckling. This can be due to an abnormality of the mouth or simply to a lack of coordination of the jaw muscles. In addition, the mother may not be placing her breast into the infant's mouth properly.
- Scheduling problems. Very young infants need to be breastfed very frequently, about every 2 to 3 hours during the first month of life. As the baby gets older he or she will eat more at each feeding and need to feed less frequently. Newborns should not go more than 4 hours between feedings, even during the night. Scheduling may become a problem for women who work outside the home, as they often find that their milk flow diminishes after they return to work.
- Nipple and breast problems. Infants may have difficulty latching on to inverted or flat nipples. Other structural problems, such as insufficient mammary glandular tissue, may result in reduced milk production. In addition, cracked and sore nipples and breast infection (mastitis) can make nursing painful.
- Retained placenta. If a woman's milk has not come in, and she continues to experience abnormal bleeding after delivery, she may still be retaining pieces of the placenta within her uterus.
- Stomach sleeping. A nursing mother who sleeps on her stomach may experience decreased milk production due to the extended pressure on her breasts.

WWW.BOOKBAZ.IR

- Stress and fatigue. New mothers need proper rest in order to produce an adequate milk supply. The ability to relax is also fundamental to proper breastfeeding. Women who are stressed can have difficulty achieving milk "let-down," the sensation of the mammary glands releasing milk.
- Psychological issues. Some women are unable to breastfeed because of preconceived notions about the practice, or ideas instilled by their parents and peers that have put up a psychological barrier for them. Many women are uncomfortable breastfeeding in public and may even abandon the practice because they do not want to be shut off from others or feel squeamish about feeding their babies even in front of friends and family members.

Diagnosis

Breastfeeding problems are usually first suspected when an infant is not gaining weight as expected. Most babies lose some weight in the first few days of life. However, they should regain the weight quickly and be back at their birth weight at two weeks of age. An average weight gain of 6–8 ounces per week should be maintained through the second or third month. After that, growth charts can demonstrate whether the child is gaining adequate weight.

Failure to gain weight regularly can be a sign of many different problems with a newborn, some very serious. The baby's pediatrician can do a variety of tests and take a complete history of the baby including regularity of soiling diapers, frequency of feeding, fussiness, and other factors. The tests and history can help the pediatrician determine if a problem with breastfeeding is causing the lack of weight gain.

Once a breastfeeding problem has been established, a healthcare practitioner will ask questions about the baby's feeding schedule and may observe the mother's breastfeeding technique to determine if an improper latching-on technique or inadequate suckling is causing the difficulty. **Lactation** counselors may be helpful in diagnosing these problems. Further **physical examination** and tests may be necessary to determine if structural breast problems or placental fragments are the root of the problem.

Treatment

Proper treatment for breastfeeding difficulties depends on the cause of the problem.

Inadequate milk production

Milk production can be boosted in several ways. The easiest way is for the mother to encourage more frequent feedings at the breast. If this is impractical or the baby does not cooperate, milk production often can be increased through intermittent use of a breast pump, a device that expresses milk from the breast. Breast pumps are available in manual and electric models and can be purchased or rented. Pumped breast milk can be bottled or frozen and fed by bottle to the baby at a later time, although if milk production is a problem the mother will probably want to put the baby to the breast at every opportunity.

Milk thistle, or *Silybum marianum*, is sometimes prescribed to promote increased breast milk secretion. Although the herb is considered safe for nursing mothers, it should be acquired from a reputable source and prescribed by an herbalist, naturopathic physician, or other healthcare professional familiar with its use.

Each breast contains both foremilk and the richer, fat-laden hindmilk. Infants need the nutrients and fat of the hindmilk, but must get through the foremilk to reach it. This can be encouraged by the mother completely emptying one breast before starting the baby on the other one. If the baby does not completely empty a breast, the job can be finished with the aid of a breast pump. The next time the mother nurses, she should start the child on the opposite breast.

Latching problems

To ensure proper breastfeeding, the mother should encourage the baby to latch on to the entire nipple, with his or her lips past the outside perimeter of the areola, before starting to suck. The mother will

KEY TERMS

Areola—The pigmented, circular area surrounding the nipple of each breast.

Lactation—Secretion of milk from the breasts; the act of breastfeeding.

Latch-on—The process whereby the baby opens the mouth widely and first exerts negative pressure on the mother's nipple and then positive pressure. Good latch-on will result in adequate transfer of milk into the baby's mouth and prevent sore nipples from developing.

Postpartum—Refers to the six-week period after childbirth.

Prolactin—A hormone secreted after delivery that stimulates the production of milk.

likely have to guide the breast into the baby's mouth, and repositioning may be required.

Practice makes perfect, and sometimes all an infant needs to improve his latching and suckling technique is time. If the baby has a structural problem in the mouth, such as a **cleft palate**, a breast pump may be required to keep milk production going. In some cases where suckling does not improve, feeding with a supplementary **nutrition** system may be required. The system consists of a feeding bottle containing the mother's own breast-pumped milk, and two tubes that run down from the bottle and attach to the nipples. Milk flows easily from the tubes with a weak sucking action from the baby. Both baby and mother can still maintain closeness while providing the baby with adequate milk flow.

Scheduling problems

Nursing newborns who are sleeping through the night without a feeding are probably not getting enough milk. They should go no longer than four hours at night without feeding, and may require waking to ensure they get enough to eat.

Women who have returned to work can use a portable breast pump at least once during the workday to encourage sustained milk flow and to store milk for their babies to eat during their time away from home.

Nipple and breast problems

Liquid **vitamin E** applied regularly to sore or cracked nipples can soothe the **pain** and help the healing process. Women who think they have a breast infection should see their healthcare provider immediately, as they will probably require a course of **antibiotics**.

Women with inverted nipples may find that the baby has a hard time latching on. Inverted nipples do not usually preclude breastfeeding, but may require extra time and effort to help the baby learn to feed effectively. A lactation consultant can help the woman find a technique that works for her and her baby.

Retained placenta

Minor surgery known as a **dilatation and curettage** (D and C) usually is required to remove pieces of placenta that have been retained by the uterus. Once the placenta has been removed, prolactin levels normally rise, stimulating milk production.

Stress and fatigue

Relaxation exercises, **yoga**, **meditation**, massage, and **aromatherapy** can all be useful tools for relieving **stress**. Women should establish a quiet, restful environment for nursing. Warm compresses to the breast may also assist in milk let down. If it is feasible, taking naps when the baby is sleeping can help to ease the **fatigue** caused by nighttime feedings.

Psychological issues

Support from family and friends is necessary for any new mother, especially one that chooses to nurse her child. If no familiar support network exists, women may seek help from groups for nursing mothers such as the La Leche League.

Many hospitals offer mothers and their spouses classes on breastfeeding techniques and nursing issues. Women who have negative feelings about breastfeeding may find classes helpful in overcoming these issues.

Expected results

In most cases, treatment for breastfeeding problems is successful and mother and baby do well. Other women may be able to breastfeed in limited amounts, but require supplementing their child's diet with formula to ensure proper weight gain and adequate nutrition. For a small percentage of women, physical problems or psychological issues may prevent successful nursing altogether.

Prevention

The best way for a new mother to prevent nursing problems is to take care of herself by eating right, drinking plenty of fluids, and staying rested and relaxed. It is important, because breastfeeding incidence and duration are both believed to be associated with reduced risk of some female cancers and possibly with improved bone health later in life.

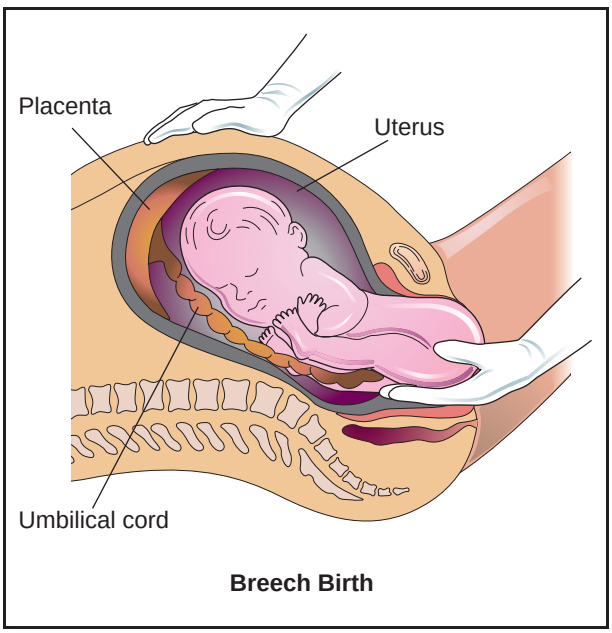
Breech birth

Definition

In a breech birth, the presenting part of the fetus, or the part that enters the woman's birth canal first, is the buttocks or leg(s).



Approximately 4 in 100 babies will start labor in the breech (buttocks first) position. While this is a potentially dangerous situation, many full-term babies can be safely delivered from the breech position. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Demographics

In almost 97% of vaginal births, the head is the part of the baby to be born first (i.e., vertex presentation). During a woman's **pregnancy**, the fetus moves freely inside the uterus, cushioned by the amniotic fluid. At 20 weeks of gestation, the midway point in the pregnancy, about 24% of fetuses are in a breech position. By 34 weeks, only about 7% are in a breech position. As the pregnancy progresses toward term (37–42 weeks), the growing fetus has less room in which to turn around, and usually remains more in an inverted (head down) position. However, in about 3–4% of births, the buttocks or feet present first.

Description

There are three types of breech presentations:

- Complete breech, in which the buttocks present first, the baby's thighs are tight against the abdomen, the legs are crossed, and the feet are flexed. In this position, the fetus is curled up tightly in a ball.
- Frank breech, in which the knees are straight (i.e., not bent), and the legs are held tightly against the abdomen and head. This breech position comes closest to filling the pelvic inlet, as would the fetus's head.
- Footling breech, in which one or both legs enter the birth canal first. The fetus appears to be standing in an upright position.

Risk factors

Risks of a vaginal breech delivery include:

- Prolapse of the umbilical cord. This is especially true in a footling presentation, where the feet and legs are small and provide room for the umbilical cord to slip alongside and into the birth canal. Any pressure on the cord compresses the sides of the cord, decreasing blood flow and oxygen to the fetus. This may result in anoxia.
- Entrapment of the head. This occurs when the body passes through the cervix, but the head, which is the largest part of the body, cannot fit through the cervical opening. This may occur because the cervix was incompletely dilated at the time of the birth, or when the head is larger than the pelvic opening.
- Trauma to the head or neck of the neonate during delivery. This could result in permanent brain damage or paralysis of the infant.
- Trauma to the spine or an arm resulting in fracture of a bone.
- Meconium aspiration. The breech position may cause an early rupture of the amniotic fluid membranes, and meconium (the infant's first stool) may be

released. If the neonate breathes in any of the meconium, the baby risks obstruction of the airway by the meconium, and pneumonia.

- Dysfunctional labor. A fetal breech position can cause labor to be drawn out, exhausting the mother, and diminishing her ability to push as the time of delivery approaches.
- Higher level of perinatal morbidity and mortality.

Accurate imaging of the fetus *in utero* has decreased the number of breech births by alerting obstetricians and midwives to this presentation before delivery. A technique called external version may be used to encourage the fetus to rotate into a vertex position. However, as the practice of external version has increased, practitioners have had less experience delivering a breech baby vaginally. A successful vaginal delivery of a breech presentation depends to a great extent on the skill and experience of the practitioner.

Twins present a special challenge and take one of several possible birth positions:

- Vertex-vertex. In this, the safest of positions for delivery, the twins both present in the vertex, or head-down position. It occurs in about 40%–45% of twin births.
- Vertex-breech or breech-vertex. This position offers the most efficient use of the uterine space, but is not the best presentation for delivery. Vertex-breech and vertex-transverse positions occur in about 35%–40% of twin births. Breech-vertex positioning occurs in about 15%–20% of births.
- Breech-breech presentation occurs in about 15%–20% of twin births, and almost always results in cesarean-section birth.

If the second twin entering the birth canal is the larger, there will be a concern that neonate may become stuck because the smaller, first twin did not adequately enlarge the cervical opening. Twins are often born prematurely, and are smaller than a full-term infant. The more premature the infant, the greater the chance it will have a smaller body-to-head proportion than the full-term infant. This creates a greater hazard for breech birth, because the small body can come through a less-dilated cervix, and there is a greater chance that the head will get trapped. Accurate imaging of twin positions will play a major role in determining the safest delivery method. An external version of the second twin may be proposed. Version of the first twin is unlikely, as the procedure poses a threat to both twins.

KEY TERMS

Anoxia—An absence of oxygen.

Cephalopelvic disproportion—Occurs when the fetus's head is larger than the mother's pelvic inlet.

Meconium—The first feces passed by the newborn. If passed before birth, the fetus can inhale this material, causing medical complications.

Nuchal cord—The term used when the umbilical cord is looped around the fetus's neck in utero.

Presentation—The part of the fetus's body that enters into the birth canal first.

Prolapsed umbilical cord—A cord that has fallen into the birth canal and may even hang out of the mother's vagina. This can cause compression of the cord and lead to decreased oxygen and blood flow to the fetus.

Transverse—A position in which the fetus lies sideways against the birth canal, with a shoulder or arm possibly entering the canal.

Causes and symptoms

The specific cause of a particular breech presentation may not be understood about 80% of the time. Causes of breech presentation may include:

- an inability of the fetus to have full movement inside the uterus
- the position of the placenta, such as a low-lying placenta previa, and a short umbilical cord
- decreased muscle tone of the fetus
- a congenital disorder of the fetus, especially neuromuscular in nature
- a space-related problem for the fetus, such as with uterine fibroids
- fetal anomaly, such as hydrocephalus
- uterine structural anomaly, such as a septum trapping the fetus in a breech position
- gestation of less than 40 weeks
- multiple gestation
- hydramnios, a condition in which excess amniotic fluid is produced and the fetus has too much room in which to move

Diagnosis

There are three primary ways in which a breech position is discovered, including imaging, position of

WWW.BOOKBAZ.IR

the fetal heartbeat, and external palpation on the mother's abdomen.

Examination

Leopold's maneuvers consist of a series of four external palpations of the mother's abdomen to determine fetal position in the uterus. The fetal head is hard and can move separately from the rest of the body. The buttocks feel soft and move with the body. As the time for delivery draws near, a vaginal examination may be required, as Leopold's maneuvers can sometimes be misleading. In a vaginal examination, the baby's fontanelles are palpated.

Procedures

There are a variety of imaging technologies, varying in safety, cost, and ease of access. **Magnetic resonance imaging** (MRI) is very accurate, but is extremely expensive, not as readily available, and would rarely provide more information than an **ultrasound** to justify its use. Ultrasound is the most widely used method of imaging during pregnancy, as it uses sound waves instead of radiation, is readily available, and is cost efficient. Ultrasound is considered safe to use at all stages in pregnancy.

Treatment

When dealing with a breech presentation, there are three choices for delivery: attempt to rotate the fetus into a vertex presentation prior to delivery; attempt a trial of vaginal delivery in the breech position; or deliver by **cesarean section**. Some hospitals may not have the mother attempt a vaginal delivery and instead opt for cesarean section.

Traditional

The traditional and commonly used treatment within Western medical standards is external version. In external version, the fetus is rotated manually by the physician, who exerts pressure on the mother's abdomen to cause the fetus to somersault into the vertex position. Medication may be given to the mother to relax the uterine muscles before the procedure. The vertex position allows the fetus more mobility and decreases the chance of uterine contractions, which lead to early labor. Before attempting version, an ultrasound is performed to confirm the position of the fetus. The timing of version is important. Done too early, the fetus may rotate back into a breech position if too much space is still available. Performed at 35–37 weeks gestation, the success rate has shown to be up to 65%. In approximately 1–2% of cases, complications arise following version, leading to the need for immediate delivery via cesarean section.

Version should always be done in a hospital, where there are facilities for immediate cesarean delivery available in the cases of cord compression or **placental abruption**. Some research has indicated that giving the mother an epidural for the version procedure increases its success rate. The version can be accomplished by two healthcare professionals. Mineral oil may be applied to the mother's abdomen so that the obstetrician's hands can smoothly slide over the surface. The fetal heart rate should be monitored closely for any signs of fetal distress, and should be continued for about an hour after the procedure to assure fetal stability. Mothers who are Rh-negative may be given Rh immune globulin, which would prevent incompatibility should fetal-to-mother **transfusion** occur during the version. About 90% of babies turned by version remain in this position for delivery.

Version has risks and is contraindicated in the following situations:

- uterine structural anomalies
- third-trimester bleeding
- hydramnios, excess amniotic fluid production
- nuchal cord, or the cord around the baby's neck (not always seen on ultrasound)
- previous uterine surgery, such as cesarean section, that has weakened the uterine walls
- cephalopelvic disproportion (CPD), a condition in which the baby's head is too big for the mother's pelvic inlet, as evidenced on ultrasound or other imaging tools

Surgery

In a cesarean birth, an incision is made through the mother's abdominal wall into the uterus. The amniotic fluid membranes are broken and the neonate is extracted. A vertical incision in the uterus along the mother's abdominal midline is called a classical cut. This provides the fastest access to the infant and may be chosen in the event of an emergency delivery. The fetus can be removed from the uterus in minutes. If a woman has had the classical uterine incision, she will not be allowed to attempt a vaginal delivery in the future, because the uterine wall can rupture during the next labor. When time permits, the preferred incision is a transverse one, just above the pubic bone. This incision is sometimes referred to as a bikini cut. Healing time is decreased and may allow a woman to successfully deliver vaginally in the future.

Alternatives

The preferred mode of delivery is a vaginal birth with the fetus in vertex presentation. Attempts are made to rotate the fetus from a breech into a vertex position. One method has been to have the mother assume different positions (e.g., knee-chest) in the hope that this would cause the fetus to move into a more favorable position. Research studies have not shown this to be very successful, although periodic anecdotal accounts of success have been reported. In the November 11, 1998, issue of the *Journal of the American Medical Association,* researchers reported on the use of **traditional Chinese medicine** to cause the fetus to rotate. In this study, moxa, a combustible Chinese herb, was used over a two-week period to stimulate an **acupuncture** point on the toe. Stimulation of this point is believed to increase fetal activity, during which the fetus then moves into the vertex position. After two weeks of treatment with moxa, 75% of the 130 fetuses studied rotated into the vertex position. Only 48% of the control (no intervention, just routine obstetrical care) fetuses rotated. However, the results of this study have not been replicated.

Attempted vaginal delivery

During a breech birth more nursing personnel may be needed to assist the obstetrician and provide support for the mother. A neonate that has been in a breech position *in utero* may maintain an unusual position for a few days after birth. An explanation by the nurse can greatly reduce the mother's concern that there is something wrong with her baby.

When a vaginal breech birth is attempted, the pace of the delivery is very important. Fetal heart rate and uterine contractions need to be closely monitored. During a vertex vaginal delivery, the head is molded coming down the birth canal, and the labor process slows the pace of the delivery. In a breech vaginal birth, the smaller body may slip more quickly through the canal. If the head becomes caught, fetal **anoxia** (lack of oxygen) can occur. The head does not mold during a rapid breech birth, and if the neonate is allowed to deliver quickly, perhaps due to a detected prolapsed cord, the rapid change in pressure can result in intracranial hemorrhage. To assist the breech delivery, the mother may be asked to assume a squatting position, as this increases the birth canal volume by about 28%. (This position is not popular in the United States.) Forceps may be used to protect the neonate's neck and head from **trauma** and to assist in the delivery. If the vaginal birth attempt causes fetal distress, an emergency cesarean delivery may be required.

Prognosis

About half the attempts of a vaginal breech delivery result in a cesarean birth. Discovery of breech presentation before the time of delivery allows attempts to be made to rotate the fetus. If these attempts prove unsuccessful, a cesarean birth can then be scheduled. A scheduled cesarean allows the mother and her partner to be informed and participate, to some degree, in the process. **Anesthesia** can be chosen that allows the mother to be awake during the birth of her child. If emergency cesarean delivery is required, the mother is given a general anesthesia to shorten the time required to extract the fetus in distress. If complications do not occur, the prognosis is excellent.

Prevention

None of the known causes of breech presentation is preventable, and in many breech presentations, there is no known cause. While it is not possible to prevent this presentation, attempts such as version are made to prevent a breech delivery, or to minimize its inherent risks.

Bronchiectasis

Definition

Bronchiectasis is a condition in which an area of the bronchial tubes is permanently and abnormally widened (dilated), with accompanying infection.

Description

The bronchial tubes are the networks of branching tubes that deliver air to the tiny sacs of the lungs (alveoli). In bronchiectasis, the diameter of the bronchi is unusually large. Examination of the walls of the bronchial tubes reveals destruction of the normal structural elements, with replacement by scar tissue. Pus collects within the bronchi, and the normal flow of oxygen into the lungs, and carbon dioxide out of the lungs (air exchange) is impaired. The bronchi show signs of inflammation, with swelling and invasion by a variety of immune cells. The inflamed areas show signs of increased growth of blood vessels. The area of the lung that should be served by a diseased bronchial tube is also prone to inflammation and infection.

Causes and symptoms

Prior to the widespread use of immunizations, bronchiectasis was often the result of a serious infection with either **measles** or whooping **cough**. Currently, viruses that cause **influenza** (flu) or influenza-like syndromes, as well as a number of bacteria may precede the development of bronchiectasis. Patients who have been infected with **tuberculosis** or the virus that causes **AIDS** (HIV or human **immunodeficiency** virus) also have an increased chance of bronchiectasis.

Colorized bronchogram of lungs—right tree has almost no structure, caused by chronic inflammation. *(Mehau Kulyk/ Photo Researchers, Inc.)*

A number of pre-existing conditions may cause an individual to be more susceptible than normal to infection, with increased risk of bronchiectasis developing. These conditions include disorders of cilia and immune disorders.

Cilia are the tiny hairs that usually line the bronchial tubes. Cilia wave constantly, sweeping the bronchial tubes clean of bacterial or viral invaders and cleaning away excess secretions (mucus, sputum) that may be produced by the bronchi. When these cilia are abnormal or absent at birth, various bacterial or viral invaders may remain in the respiratory tract, multiply, and cause serious infections.

Immune disorders include decreased production of certain immune chemicals (immunoglobulins) that usually serve to fight off infection by bacterial or viral invasion. When these immunoglobulins are not produced in large enough quantity, bacterial and viral invaders are not effectively killed off, and infection occurs.

Other causes of bronchiectasis include an abnormally blocked (obstructed) airway. This can be due to tumor growth within the bronchial tube, or due to a child accidentally inhaling a small object, which then blocks off the bronchial tube. People with the disease called **cystic fibrosis** (CF) often have their bronchial tubes obstructed by the thick, sticky mucus that is a hallmark of CF. Toxic exposures (breathing ammonia, for example) can harm the bronchi and lead to bronchiectasis. An extreme allergic response of the immune system to the presence of certain fungi (especially one called *Aspergillus*) can also damage the bronchial tubes enough to result in bronchiectasis.

Symptoms of bronchiectasis include constant cough and the production of infected sputum (sputum is a mixture of mucus and pus), which may be bloody. In some cases, there may be **wheezing** and **shortness of breath**. The constant, low level of infection may flare, resulting in increased production of sputum, worsening of the cough, and **fever**. The area of the lung served by the affected bronchial tube may become severely infected, resulting in **pneumonia**.

Diagnosis

Chest x ray may reveal evidence of bronchiectasis, and CT scans are particularly good at revealing the thick, dilated bronchial walls of bronchiectasis. Sputum will need to be collected and cultured (grown in a laboratory dish) in order to examine it microscopically for the specific type of organism responsible for infection. A careful search for other underlying diseases is important, looking in particular for ciliary abnormalities, cystic fibrosis, or immunoglobulin deficiencies.

KEY TERMS

Bronchi—The network of tubular passages that carry air to the lung and allow air to be expelled from the lungs.

Cilia—Hair-like projections that line the bronchial tubes (also present in other areas of the body). Normal cilia beat consistently, sweeping the bronchi clean of bacteria, viruses, and mucus.

Treatment

Treatment should involve efforts to resolve any underlying disorder. Infections will require **antibiotics**; obstruction may require the removal of a foreign object or tumor. Medications are available to help thin the sputum, so that it can be more effectively coughed up. Rhythmic clapping on the chest and back while the patient assumes a number of positions (head down, primarily) may help the lungs to drain more effectively. This is called **chest physical therapy**, or percussion and postural drainage.

When a particular area of the lung is constantly and severely infected, surgery may be needed to remove it. When bleeding occurs from irritated bronchial tubes and overgrown bronchial blood vessels, surgery may be required either to remove an area of the bronchial tube, or to inject the bleeding blood vessel with a material to stop the bleeding.

In some patients, bronchiectasis eventually leads to a constantly low level of blood oxygen, despite other treatments. These patients usually have an associated increase in the size of the right side of their hearts, along with a decrease in the heart's ability to pump blood through the lungs. Some patients with extremely severe symptoms and disability have been treated with **lung transplantation**.

Prognosis

Prognosis varies widely, depending on how widespread or focal the bronchiectasis, and on the presence of other underlying disorders.

Rosalyn Carson-DeWitt, MD

Bronchiolitis

Definition

Bronchiolitis is an acute viral infection of the small air passages of the lungs called the bronchioles.

Demographics

Bronchiolitis is extremely common. It occurs most often in children between the ages of two and 24 months, with peak infection occurring between three and six months of age. About 25% of infants have bronchiolitis during their first year, and 95% have had the disease by their second birthday. Bronchiolitis occurs more often in boys than girls, with boys being hospitalized at 1.5 times the rate of girls. In temperate climates, bronchiolitis peaks from winter to late spring. In subtropical climates, the disease peaks from October to February.

Description

Bronchiolitis is an acute inflammation of the upper and lower respiratory tract. In children with bronchiolitis, the small airways (bronchioles) can become blocked. Infants, especially those born prematurely, and toddlers are at risk because their airways are so small and easily obstructed. Bronchiolitis makes it difficult to breathe. The child coughs and wheezes. The danger in bronchiolitis arises from an inability to get enough oxygen in and out of the lungs. Bronchiolitis can be fatal to the very young.

Risk factors

Children who attend daycare or who live in crowded conditions and those who are exposed to secondhand smoke at home are more likely to develop bronchiolitis. Premature infants and children born with heart and lung defects or HIV/AIDS are more likely to have severe, life-threatening infections. Bronchiolitis is a significant cause of respiratory disease worldwide. The World Health Organization (WHO) has funded research to develop a vaccine against the disease, but attempts have been unsuccessful.

Causes and symptoms

Bronchiolitis is caused by several different viruses. The most common of these is respiratory syncytial virus (RVS), which is responsible for about 100,000 hospitalizations of children under age four each year. Two subtypes of RSV have been identified, one of which causes most of the severe bronchiolitis infections. In addition, bronchiolitis can be caused by

WWW.BOOKBAZ.IR

KEY TERMS

Bronchiole—A thin air passage in the lung that branches off a larger airway.

Congenital—A condition that is present at birth.

influenza, parainfluenza, and adenoviruses, all of which are common from fall through spring. These viruses are spread in tiny drops of fluid from an infected person's nose and mouth through direct contact, such as shaking hands or kissing. The viruses can also live several hours on countertops, toys, or used tissues and easily infect people who handle contaminated items. The time from infection to the appearance of symptoms varies from two to seven days.

Bronchiolitis affects individuals differently depending on their age. In adults, older children, and some infants, bronchiolitis viruses cause symptoms similar to a mild cold—runny nose, stuffy head, and mild **cough**. The lungs are not involved, and these symptoms clear up without any medical treatment. In some children under age two, the cold-like upper respiratory symptoms worsen after a day or two. The lung tissue begins to swell and produce mucus, and the cells lining the bronchioles begin to slough off into the air passages. As the airways narrow from swelling and mucus accumulation, breathing becomes difficult, and the child makes a **wheezing** or whistling sound with each breath. Lung involvement can occur quite rapidly.

The most common signs of bronchiolitis involve the infant's struggle to breathe. The child may take 50–60 breaths per minute and may develop brief periods when they stop breathing (apnea) and begin to turn blue (**cyanosis**). This occurs most often in babies who were born very prematurely or who are under six weeks of age and babies with congenital heart and lung problems and compromised immune systems. Babies may also stop eating, because it is becomes difficult for them to swallow and breathe at the same time. They may have a low **fever**, cough, and **vomiting**.

Diagnosis

Examination

Bronchiolitis is usually diagnosed through a **physical examination** by a pediatrician or family physician. The physician often finds an increased heart rate; rapid, labored breathing; and crackles in the lungs when the child inhales. Signs of ear infection (**otitis media**) and throat infection (pharyngitis) are sometimes present.

Tests

Although laboratory tests are available that can within in a few hours confirm the presence of RSV, these tests are not routinely necessary. The oxygen level in the blood may be measured through pulse oximetry in babies who are having difficulty breathing. Inadequate oxygen in the blood is an indication that hospitalization is necessary. Chest x rays may be done on severely ill children to rule out other conditions.

Procedures

More invasive procedures are not usually necessary unless required for further diagnosis or treatment of an accompanying illness or complication.

Treatment

Traditional

The degree of respiratory distress determines treatment. Individuals with mild symptoms are treated as if they have a cold with rest, fluids, and a cool air humidifier. Babies who are struggling to breathe may be hospitalized and given supplemental humidified oxygen. Their breathing is monitored and, if necessary, fluids are given intravenously to prevent **dehydration**. Occasionally, infants need mechanical ventilation to fill and empty the lungs until the airways open.

Drugs

As of 2010, there were no drugs that were substantially effective in treating bronchiolitis.

Children with compromised immune systems from diseases such as congenital HIV/AIDS and transplant patients are at highest risk for severe infections, serious complications, and death. Children with congenital heart and lung disorders are also at higher risk, as are infants under six weeks old. These high-risk children may be admitted to pediatric intensive care units and treated with ribvarin (Virazole), a drug that keeps the virus from reproducing. This drug is reserved for the most critical cases.

Alternatives

Although there are alternative treatments for cold symptoms, such as **echinacea** and zinc, parents should consult their health practitioner about the appropriateness of using these treatments in very young children.

Prognosis

The majority of children who get bronchiolitis, even severe infections, recover without complications in one

to two weeks, although **fatigue** and a light cough may linger longer. About 60% of people develop only cold-like symptoms without lung involvement. However, the disease accounts for about 100,000 pediatric hospitalizations and 4,500 deaths each year. Deaths usually occur because medical care is not sought soon enough.

While many viral illnesses, such as **chickenpox**, can be contracted only once, after which individuals develop immunity, people can get bronchiolitis multiple times. However, after the first infection, the symptoms are usually mild.

Prevention

The viruses that cause bronchiolitis spread very easily, making prevention difficult. Common sense measures such as frequent hand washing and keeping children away from crowds and sick individuals are only partially effective. Certain very high-risk babies can be treated during the peak virus season with monthly injections of antiviral immunoglobulins to protect against RSV infection. These injections cost several thousand dollars per child per season and are reserved for children whose life could be at risk if they became infected. Antiviral immunoglobulins are used only for prevention and are not effective as a treatment once the infection has been acquired.

Bronchitis

Definition

Bronchitis is an inflammation of the air passages between the nose and the lungs, including the windpipe or trachea and the larger air tubes of the lung that bring air in from the trachea (bronchi). Bronchitis can either be of brief duration (acute) or have a long course (chronic). Acute bronchitis usually is caused by a viral infection, but also can be caused by a bacterial infection; it can heal without complications. Chronic bronchitis is a sign of serious lung disease that may be slowed but cannot be cured.

Demographics

Acute bronchitis is extremely common. Worldwide, it is one of the top five reasons for a child to see a doctor. Overall, about 90% of people with bronchitis access medical care for their illness. The National Center for Health Statistics estimates that about 10 million Americans develop bronchitis each year, ranking as ninth most common illness. In European studies, as many as 20% of school-age children developed bronchitis.

Anyone can get acute bronchitis, but infants, young children, and the elderly are more likely to get the disease because people in these age groups generally have weaker immune systems. Smokers and people with heart or other lung diseases are also at higher risk of developing acute bronchitis. Individuals exposed to chemical fumes or high levels of air pollution also have a greater chance of developing acute bronchitis.

Chronic bronchitis is a major cause of disability and death in the United States. The American Lung Association estimates that about 14 million Americans have the disease. Like acute bronchitis, chronic bronchitis is an inflammation of airways accompanied by coughing and spitting up of phlegm. In chronic bronchitis, these symptoms are present for at least three months in each of two consecutive years.

Description

Although acute and chronic bronchitis are both inflammations of the air passages, their causes and treatments are different. Acute bronchitis is most prevalent in winter. It usually follows a viral infection, such as a cold or the flu, and can be accompanied by a secondary bacterial infection. Acute bronchitis resolves within two weeks, although the **cough** may persist longer. Acute bronchitis, like any upper airway inflammatory process, can increase a person's likelihood of developing **pneumonia**.

WWW.BOOKBAZ.IR

Chronic bronchitis is caused by inhaling bronchial irritants, especially cigarette smoke. Until recently, more men than women developed chronic bronchitis, but as the number of women who smoke has increased, so has their rate of chronic bronchitis. Because this disease progresses slowly, middle-aged and older people are more likely to be diagnosed with chronic bronchitis.

Chronic bronchitis is one of a group of diseases that fall under the name **chronic obstructive pulmonary disease** (COPD). Other diseases in this category include **emphysema** and chronic asthmatic bronchitis. Chronic bronchitis may progress to emphysema, or both diseases may be present together.

Risk factors

Smoking, heart or lung disease, and exposure to chemical fumes or high levels of air pollution increase an individual's risk for bronchitis. Infants, young children, and the elderly are also at greater risk because they are more likely to have a weak immune system.

KEY TERMS

Acute—Disease or condition characterized by the rapid onset of severe symptoms.

Bronchi—The larger air tubes of the lung that bring air in from the trachea.

Chronic—Disease or condition characterized by slow onset over a long period of time.

Chronic obstructive pulmonary disease (COPD)—Used to describe chronic lung diseases, such as chronic bronchitis, emphysema, and asthma.

Emphysema—A chronic obstructive pulmonary disease in which the destruction of air sac walls form abnormally large air sacs that have reduced gas exchange ability and tend to retain air within the lungs. Symptoms include labored breathing, the inability to forcefully blow air out of the lungs, and an increased susceptibility to respiratory tract infections.

Causes and symptoms

Acute bronchitis

Acute bronchitis usually begins with the symptoms of a cold, such as a runny nose, sneezing, and dry cough. However, the cough soon becomes deep and painful. Coughing brings up a greenish-yellow phlegm or sputum. These symptoms may be accompanied by a **fever** of up to 102°F (38.8°C). **Wheezing** after coughing is common.

In uncomplicated acute bronchitis, the fever and most other symptoms, except the cough, disappear after three to five days. Coughing may continue for several weeks. Acute bronchitis is often complicated by a bacterial infection, in which case the fever and a general feeling of illness persist. To be cured, the bacterial infection should be treated with **antibiotics**.

Chronic bronchitis

Chronic bronchitis is caused by inhaling respiratory tract irritants. The most common irritant is cigarette smoke. The American Lung Association estimates that 80%–90% of COPD cases are caused by smoking. Other irritants include chemical fumes, air pollution, and environmental irritants, such as mold or dust.

Chronic bronchitis develops slowly over time. The cells that line the respiratory system contain fine, hairlike outgrowths from the cell called cilia. Normally, the cilia of many cells beat rhythmically to move mucus along the airways. When smoke or other irritants are inhaled, the cilia become paralyzed or snap off. When this occurs, the cilia are no longer able to move mucus, and the airways become inflamed, narrowed, and clogged. This leads to difficulty breathing and can progress to the life-threatening disease emphysema.

A mild cough, sometimes called smokers' cough, is often the first visible sign of chronic bronchitis. Coughing brings up phlegm, although the amount varies considerably from person to person. Wheezing and **shortness of breath** may accompany the cough. Diagnostic tests show a decrease in lung function. As the disease advances, breathing becomes difficult and activity decreases. The body does not get enough oxygen, leading to changes in the composition of the blood.

Diagnosis

Examination

Initial diagnosis of bronchitis is based on observing the patient's symptoms and **health history**. The physician listens to the patient's chest with a stethoscope for specific sounds that indicate lung inflammation, such as moist rales and crackling, and wheezing, which indicates airway narrowing. Moist rales consist of a bubbling sound heard with a stethoscope. The sound is caused by fluid secretion in the bronchial tubes.

Tests

A **sputum culture** may be performed, particularly if the sputum is green or has blood in it, to determine

whether a bacterial infection is present and to identify the disease-causing organism so that an appropriate antibiotic can be selected. Normally, the patient is asked to cough deeply, then spit the material that comes up from the lungs (sputum) into a cup. This sample is then grown in the laboratory to determine which organisms are present. The results are available in two to three days, except for tests for **tuberculosis**, which can take as long as two months.

Procedures

Occasionally, in diagnosing a chronic lung disorder, the sample of sputum is collected using a procedure called a **bronchoscopy**. In this procedure, the patient is given a local anesthetic, and a tube is passed into the airways to collect a sputum sample.

A pulmonary function test is important in diagnosing chronic bronchitis and other variations of COPD. This test uses an instrument called a spirometer to measure the volume of air entering and leaving the lungs. The test is done in the doctor's office and is painless. It involves breathing into the spirometer mouthpiece either normally or forcefully. Volumes less than 80% of the normal values indicate an obstructive lung disease.

To better determine what type of obstructive lung disease a patient has, the doctor may do a chest x ray, electrocardiogram (ECG), and blood tests. An electrocardiogram is an instrument used to measure the electrical activity of the heart and is useful in the diagnosis of heart conditions. Other tests may be used to measure how effectively oxygen and carbon dioxide are exchanged in the lungs.

Treatment

Acute bronchitis

When no secondary infection is present, acute bronchitis is treated in the same way as the **common cold**. **Home care** includes drinking plenty of fluids, resting, not smoking, increasing moisture in the air with a cool mist humidifier, and taking **acetaminophen** (Datril, Tylenol, Panadol) for fever and **pain**. **Aspirin** should not be given to children because of its association with the serious illness Reye's syndrome.

Expectorant cough medicines, unlike **cough suppressants**, do not stop the cough. Instead they are used to thin the mucus in the lungs, making it easier to cough up. This type of cough medicine may be helpful to individuals suffering from bronchitis. People who are unsure about what type of medications are in over-the-counter cough syrups should ask their pharmacist for an explanation.

If a secondary bacterial infection is present, the infection is treated with an antibiotic. Patients need to take the entire amount of antibiotic prescribed. Stopping the antibiotic early can lead to a return of the infection. Tetracycline or ampicillin is often used to treat adults. Other possibilities include trimethoprim/sulfamethoxazole (Bactrim or Septra) and the newer erythromycin-like drugs, such as azithromycin (Zithromax) and clarithromycin (Biaxin). Children under age eight are usually given amoxicillin (Amoxil, Pentamox, Sumox, Trimox), because tetracycline discolors permanent teeth that have not yet come in.

Chronic bronchitis

The treatment of chronic bronchitis is complex and depends on the stage of chronic bronchitis and whether other health problems are present. Lifestyle changes, such as quitting smoking and avoiding secondhand smoke or polluted air, are an important first step. Controlled **exercise** performed on a regular basis is also important.

Drugs

Drug therapy begins with **bronchodilators**. These drugs relax the muscles of the bronchial tubes and allow increased airflow. They can be taken by mouth or inhaled using a nebulizer. A nebulizer is a device that delivers a regulated flow of medication into the airways. Common bronchodilators include albuterol (Ventolin, Proventil, Apo-Salvent) and metaproterenol (Alupent, Orciprenaline, Metaprel, Dey-Dose).

Anti-inflammatory medications are added to reduce swelling of the airway tissue. **Corticosteroids**, such as prednisone, can be taken orally or intravenously. Other **steroids** are inhaled. Long-term steroid use can have serious side effects. Other drugs, such as ipratropium (Atrovent), are given to reduce the quantity of mucus produced.

As the disease progresses, the patient may need supplemental oxygen. Complications of COPD are many and often require hospitalization in the latter stages of the disease.

Alternatives

Alternative practitioners focus on prevention by eating a healthy diet that strengthens the immune system and practicing **stress** management. Bronchitis can become serious if it progresses to pneumonia; therefore, antibiotics may be required. In addition, there are a multitude of botanical and herbal medicines that can

WWW.BOOKBAZ.IR

be formulated to treat bronchitis. Some examples include inhaling eucalyptus or other essential oils in warm steam. Herbalists recommend a tea made of mullein (*Verbascum thapsus*), coltsfoot (*Tussilago farfara*), and anise seed (*Pimpinella anisum*). **Homeopathic medicine** and **traditional Chinese medicine** may also be useful for bronchitis, and **hydrotherapy** can contribute to cleaning the chest and stimulating immune response.

Prognosis

When treated, acute bronchitis normally resolves in one to two weeks without complications, although a cough may continue for several more weeks. The progression of chronic bronchitis, on the other hand, may be slowed, and an initial improvement in symptoms may be achieved. Unfortunately, there is no cure for chronic bronchitis, and the disease can often lead to or coexist with emphysema.

Prevention

The best way to prevent bronchitis is to not begin smoking or to stop smoking. Smokers are ten times more likely to die of COPD than nonsmokers. Smokers who stop show improvement in lung function. Other preventative steps include avoiding chemical and environmental irritants, such as air pollution, and maintaining good overall health. Immunizations against certain types of pneumonia, as well as **influenza**, are an important preventative measure for anyone with lung or immune system diseases.

Bronchodilators

Definition

Bronchodilators are medicines that help open the bronchial tubes (airways) of the lungs, allowing more air to flow through them.

Purpose

People with **asthma** have trouble breathing because their airways are inflamed and become narrowed. Normally, air moves smoothly from the mouth and nose through the airways and into the tiny air sacs of the lungs as a person breathes in. Breathing out (exhaling) happens automatically when the person stops breathing in. In a person with asthma, breathing in (inhaling) is not a problem. Incoming air can slide around the blockage, because the act of breathing in makes the airways expand. The problem comes when the person with asthma tries to breathe out. The air can no longer get past the blockage, and it remains trapped in the lungs. The person can then only take shallow breaths. Bronchodilators work by relaxing the smooth muscles that line the airways. This makes the airways open wider and allows air to leave the lungs. These drugs also are used to relieve breathing problems associated with **emphysema**, chronic **bronchitis**, and other lung diseases.

Description

Some bronchodilators are inhaled, using a nebulizer or an inhalation aerosol. Others are taken as

KEY TERMS

Anti-inflammatory—Describes those medicines used to relieve swelling, pain, and other symptoms of inflammation.

Bronchitis—Inflammation of the air passages of the lungs.

Chronic—Describes a long-lasting condition. Chronic conditions often develop gradually and involve slow changes.

Emphysema—A lung disease in which breathing becomes difficult.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Nebulizer—A device that turns liquid forms of medicine into a fine spray that can be inhaled.

Sulfite—A type of preservative that causes allergic reactions in some people.

injections or by mouth. Most are available only by prescription, but a few, such as ephedrine, can be bought without a physician's prescription. Examples of bronchodilators are albuterol (Proventil, Ventolin), epinephrine (Primatene), ipratropium (Atrovent), metaproterenol (Alupent, Metaprel), and terbutaline (Brethine).

Recommended dosage

The recommended dosage depends on the type of bronchodilator and may be different for different patients. The physician who prescribed the drug or the pharmacist who filled the prescription can recommend correct dosage.

Precautions

Bronchodilators come with patient instructions that must be carefully read before using the medicine. If there is any confusion about how to use the medicine, patients should check with the physician or pharmacist. These medicines must be used exactly as directed. Taking larger than recommended doses or using the medicine too often can lead to serious side effects and even death.

If symptoms do not improve or if they get worse after using a bronchodilator, the patient should call a physician right away.

Although some bronchodilators are available without a physician's prescription, these medicines should not be used unless a physician has diagnosed the patient's condition as asthma.

Research shows that frequent bronchodilator use over time can tighten airway muscles in some people. Some physicians advise patients to consider controlling asthma with anti-inflammatory drugs including inhaled **steroids** such as beclomethasone dipropionate (Beclovent, Vanceril), flunisolide (AeroBid) or triamcinolone acetonide (Azmacort). A 2004 Canadian study has questioned a standard practice of increasing steroids after asthma attacks or worsened symptoms. Additional research in 2004 showed that people with asthma who worked closely with their physicians to self-manage their asthma had fewer attacks, which reduces the need for bronchodilators. Carefully managing asthma also reduces visits to the emergency department and hospitalizations.

Persons with diabetes should be aware that the bronchodilator epinephrine may raise their blood sugar levels.

Patients who are using an aerosol bronchodilator and an aerosol form of either ipratropium or a corticosteroid such as beclomethasone dipropionate (Beclovent, Vanceril) should use the bronchodilator first, then wait five minutes before using the other medicine. A physician should be consulted before using any other inhaled medications or other asthma medicines. The physician must determine the proper amount of time between doses.

Some bronchodilator products contain sulfites that trigger an allergic reaction in certain people. Anyone who has a sulfite allergy should read the label carefully or check with a physician or pharmacist before using a bronchodilator. Call a physician immediately if any of these signs of an allergic reaction to sulfite occur:

- bluish coloration of the skin
- flushed or red face or skin
- faintness
- severe dizziness
- increased wheezing or other breathing problems
- skin rash, hives, or itching
- swelling of the face, lips, or eyelids

Special conditions

People with certain medical conditions or who are taking certain other medicines can have problems if they use bronchodilators. Before using these drugs, a physician should be made aware of any of these conditions:

WWW.BOOKBAZ.IR

ALLERGIES. Anyone who has had unusual reactions to any bronchodilator or an inhaled form of any other drug in the past should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

Patients who are allergic to soybeans, soy lecithin, peanuts, or drugs based on atropine should not use the bronchodilator ipratropium (Atrovent).

PREGNANCY. In studies of laboratory animals, some bronchodilators cause **birth defects** or **miscarriage** when the animals are given doses many times the usual human dose. Whether these drugs cause such problems in humans in unknown. Any woman who is pregnant or plans to become pregnant should check with her physician before using a bronchodilator.

BREASTFEEDING. Some bronchodilators pass into breast milk. **Breastfeeding** mothers should check with their physicians before using bronchodilators.

OTHER MEDICAL CONDITIONS. Before using bronchodilators, people with any of these medical problems should make sure their physicians are aware of their conditions:

- glaucoma
- brain damage
- convulsions (seizures)—recently or anytime in the past
- mental illness
- Parkinson's disease
- diabetes
- heart or blood vessel diseases
- rapid or irregular heartbeat
- high blood pressure
- overactive thyroid
- enlarged prostate
- obstruction of the neck of the bladder

USE OF CERTAIN MEDICINES. Using bronchodilators with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

Side effects

Some patients have a dry or irritated throat or a **dry mouth** after using bronchodilators. To help prevent these problems, gargling and rinsing the mouth or taking a sip of water after each dose.

The most common side effects are nervousness or restlessness and trembling. These problems usually go away as the body adjusts to the drug and do not require medical treatment. Less common side effects such as bad taste in the mouth, coughing, **dizziness** or lightheadedness, drowsiness, **headache**, sweating, fast or pounding heartbeat, **muscle cramps** or twitches, nausea, **vomiting**, **diarrhea**, sleep problems, and weakness also may occur and do not need medical attention unless they do not go away or they interfere with normal activities.

More serious side effects are not common, but may occur. If any of the following side effects occur, the physician who prescribed the medicine should be contacted as soon as possible:

- chest pain or discomfort
- irregular or fluttery heartbeat
- unusual bruising
- hives or rash
- swelling
- wheezing or other breathing problems
- numbness in the hands or feet
- blurred vision

Other side effects are possible. Anyone who has unusual symptoms after using a bronchodilator should get in touch with his or her physician.

Interactions

Bronchodilators may interact with a number of other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes these drugs should let the physician know all other medicines he or she is taking. Among the drugs that may interact with bronchodilators are:

- monoamine oxidase inhibitors (MAO inhibitors) such as phenelzine (Nardil) and tranylcypromine (Parnate), used to treat depression
- other bronchodilators
- tricyclic antidepressants such as amitriptyline (Elavil) and imipramine (Tofranil)
- beta blockers such as propranolol (Inderal) and atenolol (Tenormin), used to control high blood pressure
- digitalis medicines, used to treat heart conditions, such as digoxin (Lanoxin)
- drugs, such as certain diuretics (water pills), that lower potassium levels
- ergoloid mesylates such as Hydergine, used to treat symptoms of Alzheimer's disease or multiple small stokes
- ergotamine (Cafergot, Ergostat, and other brands), used to treat migraine and cluster headaches
- the antidepressant maprotiline (Ludiomil)

The list above does not include every drug that may interact with bronchodilators. Be sure to check with a physician or pharmacist before combining bronchodilators with any other prescription or non-prescription (over-the-counter) medicine.

Bronchoscopy

Definition

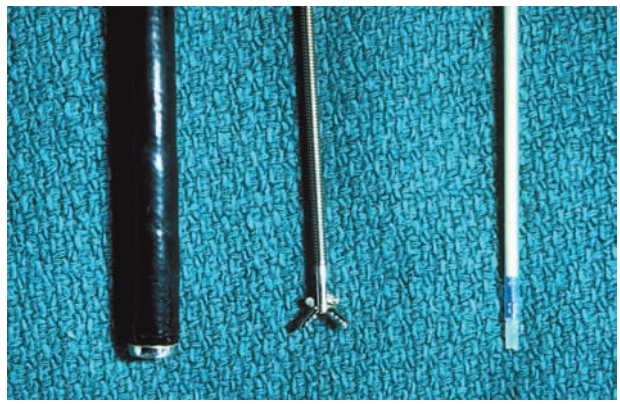
Bronchoscopy is a procedure in which a hollow, flexible tube called a bronchoscope is inserted into the airways through the nose or mouth to provide a view of the tracheobronchial tree. It can also be used to collect bronchial and/or lung secretions and to perform tissue biopsy.

Purpose

During a bronchoscopy, the physician can visually examine the lower airways, including the larynx, trachea, bronchi, and bronchioles. The procedure is used to examine the mucosal surface of the airways for abnormalities that might be associated with a variety of lung diseases. Its use may be diagnostic or therapeutic.

Bronchoscopy may be used to examine and help diagnose all of the following:

- diseases of the lung, such as cancer or tuberculosis
- congenital deformity of the lungs
- suspected tumor, obstruction, secretion, bleeding, or foreign body in the airways
- airway abnormalities, such as tracheal stenoses
- persistent cough, or hemoptysis, that includes blood in the sputum



Instruments used in bronchoscopy procedures. *(Custom Medical Stock Photo, Inc.)*

Bronchoscopy may also be used for the following therapeutic purposes:

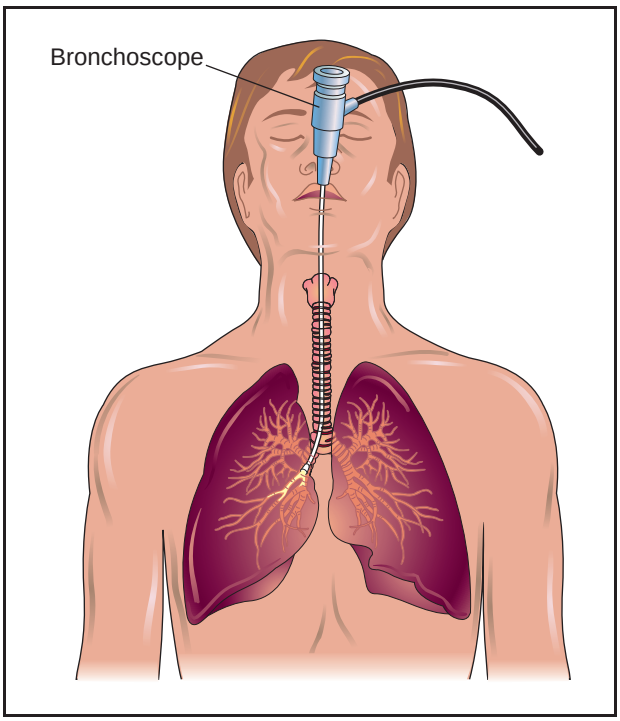
- remove a foreign body in the lungs
- remove excessive secretions
- remove tumors in the airway
- treat stenosis (narrowing) of the airways, by using balloon dilatation or placing a stent

Bronchoscopy can also be used to collect the following biopsy specimens:

- sputum
- tissue samples from the bronchi or bronchioles
- cells collected from washing the lining of the bronchi or bronchioles

If the purpose of the bronchoscopy is to take tissue samples, or biopsy, a forceps or bronchial brush are used to obtain cells. Alternatively, if the purpose is to identify an infectious agent, a bronchoalveolar lavage can be performed to gather fluid for culture purposes. If any foreign matter is found in the airways, it can be removed as well. Tumors can be debulked (made smaller) through the use of laser, electrocautery, or **cryotherapy** during the bronchoscopy. A balloon can be passed into a narrowed area of the airway and inflated in order to treat stenosis. A stent (tiny artificial tube) can be placed during bronchoscopy, in order to keep a portion of the airway open.

WWW.BOOKBAZ.IR



Bronchoscopy is a procedure in which a hollow, flexible tube is inserted into the airways, allowing the physician to visually examine the lower airways, including the larynx, trachea, bronchi, and bronchioles. It can also be used to collect specimens for bacteriological culture to diagnose infectious diseases such as tuberculosis. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

The instrument used in bronchoscopy, a bronchoscope, is a slender, flexible tube less than 0.5 in. (2.5 cm) wide and approximately 2 ft. (0.3 m) long that uses fiber-optic technology (very fine filaments that can bend and carry light). There are two types of bronchoscopes: a standard tube that is more rigid and a fiber-optic tube that is more flexible. The rigid instrument does not bend, does not see as far down into the lungs as the flexible one, and may carry a greater risk of causing injury to nearby structures. Because a standard tube can cause more discomfort than the flexible bronchoscope, it usually requires general **anesthesia**. However, it is useful for taking large samples of tissue and for removing foreign bodies from the airways. During the procedure, the airway is not blocked since oxygen can be supplied through the bronchoscope.

Demographics

Nearly 500,000 bronchoscopies are performed annually in the United States. According to the National Cancer Institute, cancer of the lung and bronchi is the second most common cancer among both men and women and is the leading cause of cancer death in both sexes in the United States. Among men, lung cancer incidence rates per 100,000 people range from a low of approximately 14 among American Indians to a high of 117 among African Americans. Between these two extremes, rates fall into two groups, ranging from 42 to 53 for Hispanics, Japanese, Chinese, Filipinos, and Koreans, and from 71 to 89 for Vietnamese, Caucasians, Alaska Natives, and Hawaiians. The range among women is much narrower, from a rate of about 15 among Japanese to nearly 51 among Alaska Natives, only a three-fold difference. Rates for the remaining female populations fall roughly into two groups with low rates of 16–25 for Korean, Filipino, Hispanic, and Chinese women, and rates of 31–44 among Vietnamese, Caucasian, Hawaiian, and African American women. The rates among men are about two to three times greater than the rates among women in each of the racial/ethnic groups.

Description

Bronchoscopy is usually performed in an **endoscopy** room, but may also be performed at the bedside. The patient is placed on the back or sits upright. A pulmonologist, a specialist trained to perform the procedure, sprays an anesthetic into the patient's mouth or throat. When anesthesia has taken effect and the area is numb, the bronchoscope is inserted into the mouth and passed into the throat. If the bronchoscope is passed through the nose, an anesthetic jelly is inserted into one nostril. While the bronchoscope is moving down the throat, additional anesthetic is put into the bronchoscope to anesthetize the lower airways. The physician observes the trachea, bronchi, and the mucosal lining of these passageways looking for any abnormalities that may be present. If samples are needed, a bronchial lavage may be performed, meaning that a saline solution is used to flush the area prior to collecting cells for laboratory analysis. Very small brushes, needles, or forceps may also be introduced through the bronchoscope to collect tissue samples from the lungs. If the procedure is therapeutic in nature, laser, electrocautery, cryotherapeutic, or balloon dilatation instruments may be passed through the bronchoscope, and a stent may be placed.

Preparation

The patient should fast for 6 to 12 hours prior to the procedure and refrain from drinking any liquids the day of the procedure. **Smoking** should be avoided for 24 hours prior to the procedure, and patients should also avoid taking any **aspirin** or ibuprofen-type medications. The bronchoscopy itself takes about 45–60 minutes. Prior to the bronchoscopy, several tests are usually done, including a chest x ray and blood work.

KEY TERMS

Anesthetic—A drug that causes loss of sensation. It is used to lessen the pain of surgery and medical procedures.

Biopsy—Procedure that involves obtaining a tissue specimen for microscopic analysis to establish a precise diagnosis.

Bronchi—The network of tubular passages that carry air to the lungs and allow air to be expelled from the lungs.

Bronchioles—Small airways extending from the bronchi into the lobes of the lungs.

Bronchoalveolar lavage—Washing cells from the air sacs at the end of the bronchioles.

Computed tomography (CT)—A special radiographic imaging technique that uses a computer to acquire multiple x rays into a two-dimensional sectional image.

Emesis basin—A basin used to collect sputum or vomit.

Endoscope—A highly flexible viewing instrument.

Endoscopy—The visual inspection of any cavity of the body using an endoscope.

Hemoptysis—The expectoration of blood or of blood containing sputum.

Larynx—The voice box.

Lavage—Washing out.

Neoplasm—A new growth or tumor.

Sputum—Matter ejected from the lungs, bronchi, and trachea through the mouth.

Stenosis—Narrowing of a duct or canal.

Trachea—The windpipe.

Tracheobronchial—Pertaining both to the tracheal and bronchial tubes or to their junction.

Sometimes a bronchoscopy is done under general anesthesia, in which case the patient will have an intravenous (IV) line in the arm. More commonly, the procedure is performed under local anesthesia, which is sprayed into the nose or mouth. This is necessary to inhibit the gag reflex. A sedative may also be given. A signed consent form is necessary for this procedure.

Aftercare

After the bronchoscopy, the vital signs (heart rate, blood pressure, and breathing) are monitored. Sometimes patients have an abnormal reaction to anesthesia. Any sputum should be collected in an emesis basin so that it can be examined for the presence of blood. If a biopsy was taken, the patient should not **cough** or clear the throat as this might dislodge any blood clot that has formed and cause bleeding. No food or drink should be consumed for about two hours after the procedure or until the anesthesia wears off. There is a significant risk for **choking** if anything (including water) is ingested before the anesthetic wears off and the gag reflex has returned. To test if the gag reflex has returned, a spoon is placed on the back of the tongue for a few seconds with light pressure. If there is no gagging, the process is repeated after 15 minutes. The gag reflex should return in one or two hours. Ice chips or clear liquids should be taken before the patient attempts to eat solid food. Patients should be informed that the throat may be irritated for several days.

Patients should notify their healthcare provider if they develop any of these symptoms:

- hemoptysis (coughing up blood)
- shortness of breath, wheezing, or any trouble breathing
- chest pain
- fever, with or without breathing problems

Risks

Use of the bronchoscope mildly irritates the lining of the airways, resulting in some swelling and inflammation, as well as hoarseness caused from abrading the vocal cords. If this abrasion is more serious, it can lead to respiratory difficulty or bleeding of the lining of the airways.

The bronchoscopy procedure is also associated with a small risk of disordered heart rhythm (arrhythmia), heart attacks, low blood oxygen (hypoxemia), and pneumothorax (a puncture of the lungs that allows air to escape into the space between the lung and the chest wall). These risks are greater with the use of a rigid bronchoscope than with a fiber-optic bronchoscope. If a rigid tube is used, there is also a risk of chipped teeth. The risk of transmitting **infectious disease** from one patient to another by the bronchoscope is also present. The Centers for Disease Control (CDC) reported cases of patient-to-patient transmission of infections following bronchoscopic procedures using bronchoscopes that were inadequately reprocessed by the automated endoscope reprocessing (AER) system. Investigation of the incidents revealed inconsistencies between the reprocessing instructions provided by the manufacturer of the bronchoscope

WWW.BOOKBAZ.IR

and the manufacturer of the AER; or that the bronchoscopes were inadequately reprocessed.

Results

If the results of the bronchoscopy are normal, the windpipe (trachea) appears as smooth muscle with C-shaped rings of cartilage at regular intervals. There are no abnormalities either in the trachea or in the bronchi of the lungs.

Bronchoscopy results may also confirm a suspected diagnosis. This may include swelling, ulceration, or deformity in the bronchial wall, such as inflammation, stenosis, or compression of the trachea, neoplasm, and foreign bodies. The bronchoscopy may also reveal the presence of atypical substances in the trachea and bronchi. If samples are taken, the results could indicate cancer, disease-causing agents, or other lung diseases. Other findings may include constriction or narrowing (stenosis), compression, dilation of vessels, or abnormal branching of the bronchi. Abnormal substances that might be found in the airways include blood, secretions, or mucous plugs.

Morbidity and mortality rates

Bronchoscopy belongs to the group of procedures associated with highest inpatient mortality with a 12.7% mortality rate.

Alternatives

Depending upon the purpose of the bronchoscopy, alternatives may include a chest x ray or a computed tomography (CT) scan. If the purpose is to obtain biopsy specimens, one option is to perform surgery, which carries greater risks. Another option is percutaneous biopsy guided by CT.

Brucellosis

Definition

Brucellosis is a bacterial disease caused by members of the *Brucella* genus that can infect humans but primarily infects livestock. Symptoms of the disease include intermittent **fever**, sweating, chills, aches, and mental depression. The disease can become chronic and recur, particularly if untreated.

Description

Also known as undulant fever, Malta fever, Gibraltar fever, Bang's disease, or Mediterranean fever, brucellosis is most likely to occur among those individuals who regularly work with livestock. The disease originated in domestic livestock but was passed on to wild animal species, including the elk and buffalo of the western United States. In humans, brucellosis continues to be spread via unpasteurized milk obtained from infected cows or through contact with the discharges of cattle and goats during **miscarriage**. In areas of the world where milk is not pasteurized, such as in Latin America and the Mediterranean, the disease is still contracted by ingesting unpasteurized dairy products. However, in the United States, the widespread pasteurization of milk and nearly complete eradication of the infection from cattle has

KEY TERMS

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Chronic—Describes a disease or condition characterized by slow onset over a long period of time.

Parasite—An organism living in or on, and obtaining nourishment from, another organism.

Pasteurization—The process of applying heat, usually to milk or cheese, for the purpose of killing, or retarding the development of, pathogenic bacteria.

reduced the number of human cases from 6,500 in 1940 to less than 200 as of 2014.

Causes and symptoms

The disease is caused by several different species of parasitic bacteria of the genus Brucella. *B. abortus* is found in cattle and can cause cows to abort their fetuses. *B. suis* is most often found in hogs and is more deadly when contracted by humans than the organism found in cattle. *B. melitensis* is found in goats and sheep and causes the most severe illness in humans. *B. rangiferi* infects reindeer and caribou, and *B. canis* is found in dogs.

A human contracts the disease by coming into contact with an infected animal and either allowing the bacteria to enter a cut, breathing in the bacteria, or consuming unpasteurized milk or fresh goat cheese obtained from a contaminated animal. In the United States, the disease is primarily confined to slaughterhouse workers.

Scientists do not agree about whether brucellosis can be transmitted from one person to another, although some people have been infected from a tainted blood **transfusion** or bone marrow transplant. Newborn babies have also contracted the illness from their mothers during birth. As of 2014, it was believed that brucellosis can also be transmitted sexually.

The disease is not usually fatal, but the intermittent fevers (a source of its nickname, "undulant fever") can be exhausting. Symptoms usually appear between five days and a month after exposure and begin with a single bout of high fever accompanied by shivering, aching, and drenching sweats that last for a few days. Other symptoms may include **headache**, poor appetite, backache, weakness, and depression. Mental depression can be so severe that the patient may become suicidal.

In rare, untreated cases, the disease can become so severe that it leads to fatal complications, such as **pneumonia** or bacterial **meningitis**. *B. melitensis* can cause miscarriages, especially during the first three months of **pregnancy**. The condition can also occur in a chronic form, in which symptoms recur over a period of months or years.

Diagnosis

Brucellosis is usually diagnosed by detecting one or more *Brucella* species in blood or urine samples. The bacteria may be positively identified using biochemical methods or using a technique whereby, if present in the sample, the brucellosis bacteria are made to fluoresce. Brucellosis may also be diagnosed by culturing and isolating the bacteria from one of the above samples. Blood samples will also indicate elevated antibody levels or increased amounts of a protein produced directly in response to infection with brucellosis bacteria.

Treatment

Prolonged treatment with **antibiotics**, including **tetracyclines** (with streptomycin), co-trimoxazole, and **sulfonamides**, is effective. Bed rest is also imperative. In the chronic form of brucellosis, the symptoms may recur, requiring a second course of treatment.

Prognosis

Early diagnosis and prompt treatment is essential to prevent chronic infection. Untreated, the disease may linger for years, but it is rarely fatal. Relapses may also occur.

Prevention

There is no human vaccine for brucellosis, but humans can be protected by controlling the disease in livestock. After checking to make sure an animal is not already infected, and destroying those that are, all livestock should be immunized. Butchers and those who work in slaughterhouses should wear protective glasses and clothing, and protect broken skin from infection.

Some experts suggest that a person with the disease refrain from engaging in unprotected sex until free of the disease. The sexual partners of an infected person should also be closely monitored for signs of infection.

Carol A. Turkington

Brugian filariasis *see* **Elephantiasis**

Bruises

Definition

Bruises, or ecchymoses, are a discoloration and tenderness of the skin or mucous membranes due to the leakage of blood from an injured blood vessel into the tissues. Pupura refers to bruising as the result of a disease condition. A very small bruise is called a petechia. These often appear as many tiny red dots clustered together, and could indicate a serious problem.

Description

Bruises change colors over time in a predictable pattern, so it is possible to estimate when an injury occurred by the color of the bruise. Initially, a bruise will be reddish, the color of the blood under the skin.

A close-up view of woman's bruised left eye. *(Custom Medical Stock Photo, Inc.)*

After one to two days, the red blood cells begin to break down, and the bruise will darken to a blue or purplish color. This fades to green at about day six. Around the eighth or ninth day, the skin over the bruised area will have a brown or yellowish appearance, and it will gradually diminish back to its normal color.

Long periods of standing will cause the blood that collects in a bruise to seep through the tissues. Bruises are actually made of little pools of blood, so the blood in one place may flow downhill after awhile and appear in another. For instance, bruising in the back of the abdomen may eventually appear in the groin; bruising in the thigh or the knee will work its way down to the ankle.

Causes and symptoms

Healthy people may develop bruises from any injury that does not break through the skin. Vigorous **exercise** may also cause bruises due to bringing about small tears in blood vessels walls. In a condition known as purpura simplex, there is a tendency to bruise easily due to an increased fragility of the blood vessels. Bruises also develop easily in the elderly, because the skin and blood vessels have a tendency to become thinner and more fragile with **aging**, and there is an increased use of medications that interfere with the blood clotting system. In the condition known as purpura senilis, the elderly develop bruises from minimal contact that may take up to several months to completely heal.

The use of nonsteroidal anti-inflammatories such as ibuprofen (Advil) and naproxen (Aleve) may lead to increased bruising. **Aspirin**, antidepressants, **asthma** medications, and cortisone medications also have this effect. The anti-clotting medications known as blood thinners, especially the drug Warfarin (Coumadin), may be the cause of particularly severe bruising.

Sometimes bruises are connected with more serious illnesses. There are a number of diseases that cause excessive bleeding or bleeding from injuries too slight to have consequences in healthy people. An abnormal tendency to bleed may be due to hereditary bleeding disorders, certain prescription medications, diseases of the blood such as leukemia, and diseases that increase the fragility of blood vessels. If there are large areas of bruising or bruises develop very easily, this may herald a problem. Other causes that should be ruled out include **liver disease**, **alcoholism**, drug **addiction**, and acquired immune deficiency syndrome (**AIDS**). Bruising that occurs around the navel may indicate dangerous internal bleeding; bruising behind the ear, called Battle's sign, may be due to a skull fracture; and raised bruises may point to autoimmune disease.

Diagnosis

Bruising is usually a minor problem, which does not require a medical diagnosis. However, faced with extensive bruising, bruising with no apparent cause, or bruising in certain locations, a physician will pursue an evaluation that will include a number of blood tests. If the area of the bruise becomes hard, an x ray may be required.

Treatment

A bruise by itself needs no medical treatment. It is often recommended that ice packs be applied on and off during the first 24 hours of injury to reduce the bruising. After that, heat, especially moist heat, is recommended to increase the circulation and the healing of the injured tissues. Rest, elevation of the affected part, and compression with a bandage will also retard the accumulation of blood. Rarely, if a bruise is so large that the body cannot completely absorb it or if the site becomes infected, it may have to be surgically removed.

Alternatives

Several types of topical applications are usually recommend to speed healing and to reduce the **pain** associated with bruises. **Vitamin K** cream can be applied directly to the site of injury. Astringent herbs such as witch hazel, *Hamamelis virginiana*, can be used. This will tighten the tissues and therefore diminish the bruising. The homeopathic remedy, *Arnica montana*, can be applied as a cream or gel to unbroken skin.

Oral homeopathic remedies may reduce bruising, pain, and swelling as well. *Arnica montana*, at 30 mL (1 oz), taken one to two times per day is highly recommended. For ledum, 30 mL (1 oz) one to two times per day is also useful.

Prognosis

The blood under the skin that causes the discoloration of bruising should be totally reabsorbed by the body in three weeks or less. At that time, the skin color should completely return to normal.

Sometimes, a bruise may become solid and increase in size instead of dissolving. This may indicate blood trapped in the tissues, which may be need to be drained. This is referred to as a hematoma. Less commonly, the body may develop **calcium** deposits at the injury site in a process called heterotopic ossification.

Prevention

Vitamin K promotes normal clotting in the blood, and therefore may help reduce the tendency to bruise easily. Green leafy vegetables, alfalfa, broccoli, seaweed, and fish liver oils are dietary sources of vitamin K. Other good foods to eat would be those containing bioflavonoids, such as reddish-blue berries. These can assist in strengthening the connective tissue, which will decrease the spread of blood and bruising. Zinc and vitamin C supplements are also recommended for this.

Bruxism

Definition

Bruxism is the habit of clenching and grinding the teeth. It most often occurs at night during sleep, but it may also occur during the day. It is an unconscious behavior, perhaps performed to release **anxiety**, aggression, or anger.

Description

Bruxism is one of the oldest disorders known, and approximately one in four adults experiences it. Most people are not aware of it before their teeth have been damaged.

Causes and symptoms

While bruxism is typically associated with **stress**, it may also be triggered by abnormal occlusion (the way the upper and lower teeth fit together), or crooked or missing teeth.

Symptoms of bruxism include: dull headaches; sore and tired facial muscles; earaches; sensitive teeth; and locking, popping, and clicking of the jaw.

During a dental examination, a dentist may recognize damage resulting from bruxism, including enamel loss from the chewing surfaces of teeth, flattened tooth

WWW.BOOKBAZ.IR

KEY TERMS

Enamel—The hard outermost surface of a tooth.

High spot—An area of a tooth or restoration that feels abnormal or uncomfortable because it hits its opposing tooth before other teeth meet.

Night guard—A removable, custom-fitted plastic appliance that fits between the upper and lower teeth to prevent them from grinding against each other.

Occlusion—The way upper and lower teeth fit together during biting and chewing.

Rolfing—Based on the belief that proper alignment of various parts of the body is necessary for physical and mental health, a technique that uses deep tissue massage and movement exercises in an attempt to bring the body into correct alignment.

Temporomandibular joint (TMJ)—The jaw joint formed by the mandible (lower jaw bone) moving against the temporal bone of the skull.

surfaces, loosened teeth, and fractured teeth and fillings. Left untreated, bruxism may lead to tooth loss and jaw dysfunction.

Diagnosis

Medical and dental histories and examinations are necessary to differentiate bruxism from other conditions that may cause similar **pain**, such as ear infections, dental infections, and temporomandibular joint (TMJ) dysfunction. However, uncommonly worn-down teeth strongly suggest a diagnosis of bruxism.

Treatment

To prevent further damage to the teeth, bruxism is treated by placing a removable, custom-fitted plastic appliance called a night guard between the upper and lower teeth. Although the clenching and grinding behavior may continue, the teeth wear away the plastic instead of each other.

In some cases, abnormal occlusion may be adjusted and high spots removed so that the teeth fit together in a more comfortable position. Missing teeth may be replaced and crooked teeth may be straightened with orthodontic treatment to eliminate possible underlying causes of bruxism. In cases where jaw muscles are very tight, a dentist may prescribe **muscle relaxants**.

Alternatives

Stress management and behavior modification techniques may be useful to break the habit of clenching and grinding teeth. Tight jaw muscles may be relaxed by applying warm compresses to the sides of the face. Herbal muscle relaxants also can be helpful. **Massage therapy** and deep tissue realignment, including **rolfing**, can assist in releasing the clenching pattern. This is a more permanent alternative treatment for bruxism.

Prognosis

Bruxism may cause permanent damage to teeth and chronic jaw pain unless properly diagnosed and promptly treated. The behavior may be eliminated if its underlying causes are found and addressed.

Prevention

Increased awareness in patients prone to anxiety, aggression, or anger may prevent the habit of bruxism from developing.

Bubonic plague *see* **Plague**

Budd-Chiari syndrome

Definition

Budd-Chiari syndrome is a rare problem that results from blood clotting in the veins flowing out of the liver (hepatic veins). The high pressure of blood in these veins leads to an enlarged liver, and to an accumulation of fluid in the abdomen, called **ascites**.

Demographics

The exact frequency of Budd-Chiari syndrome is unknown. The syndrome is seen in all races and in both males and females. It appears to be more prevalent in Asian countries, with individuals presenting

KEY TERMS

Ascites—Accumulation of fluid in the abdomen.

Biopsy—Surgical removal of a tiny bit of tissue for examination under the microscope.

Catheter—A tubular surgical instrument.

Phlebitis—Inflammation of a vein.

Polycythemia vera—An excess number of red blood cells in the blood.

Sickle cell anemia—An inherited disease in which red blood cells take an unusual shape, leading to circulation problems.

clinical symptoms during ages 30 to 40; however it may occur in children and in older individuals, as well.

Description

The liver, the largest internal organ in the human body, is responsible for many vital physiologic processes. Blood flow through the liver nourishes the liver, carries in substances that the liver will process, and carries away substances that the liver has produced. When blood cannot flow out freely from the liver, blood pressure rises in the veins of the liver, leading to **blood clots** within the liver. Also, some of the blood plasma can leak through the walls of the veins and accumulate within the abdomen (ascites).

Causes and symptoms

The major symptoms include **pain** in the upper right-hand portion of the abdomen and a buildup of fluid in the abdomen. In the United States, blood disorders are the most common causes. Among these disorders are **polycythemia vera** (an increase in the number of red blood cells) and sickle cell anemia. In parts of the world where **liver cancer** is common, a form of liver cancer is the most frequent cause.

Other causes sometimes include:

- certain infections
- use of oral contraceptives
- body changes in pregnancy and the postpartum period
- phlebitis (inflammation of a vein)
- injury to the abdomen
- a membrane web that causes blockage of the inferior vena cava

Diagnosis

Diagnosis of Budd-Chiari syndrome can be made by an internist (a specialist in diseases of the internal organs), a gastroenterologist (a specialist in the diseases of the digestive system), or a general surgeon. On **physical examination**, the doctor will note that the liver is larger than normal. Often an **ultrasound** scan of the liver will show abnormalities in the size of the liver, an abnormal pattern of the veins in the liver, and other abnormalities. A CT scan will often show similar abnormalities.

Once these abnormalities are confirmed, the key test is called hepatic vein catheterization. In this test, a narrow tube is snaked through the body until it reaches the hepatic veins. An instrument at the tip of the catheter can measure the pressure within each segment of the hepatic vein.

In some cases, a tiny amount of radioactive material is injected into a patient, and then an abnormal pattern of radioactivity in the liver can be revealed. In other cases, a **liver biopsy** enables a physician to examine cells from the liver itself. Cells damaged by Budd-Chiari syndrome have a characteristic appearance easily identifiable to a physician.

Treatment

Surgery

Most patients with Budd-Chiari syndrome must have surgery. A surgeon will re-route blood flow around the clotted hepatic vein into a large vein called the vena cava. The exact technique will depend on the specific location of the clots and other factors. In certain patients, other surgical techniques may be used. For patients who otherwise would have less than six months to live, **liver transplantation** is sometimes performed.

In a few patients, a "balloon catheter" can open the blocked blood vessels, without the need for major surgery.

Drugs

Sometimes, anti-clotting drugs such as urokinase and tissue plasminogen activator (tPA) can be used for patients with a sudden onset of clotting in the veins of the liver. These drugs do not seem to work when the clots have become established.

Prognosis

If surgery is done before permanent liver damage sets in, long-term survival is possible. In these cases, damaged liver cells can actually recover. If patients are

WWW.BOOKBAZ.IR

already very sick with **liver disease**, the surgery may not be as helpful.

Prevention

The best approach to prevention is to carefully control the blood disorders that can lead to Budd-Chiari syndrome.

Buerger's disease

Definition

Buerger's disease is an inflammation of the arteries, veins, and nerves in the legs, leading to restricted blood flow. Left untreated, Buerger's disease can lead to **gangrene** of the affected areas. Buerger's disease is also known as thromboangitis obliterans.

Causes and symptoms

The exact cause of Buerger's disease is not known. It is seen most often in young to middle-aged men (ages 20–40) who are heavy smokers of cigarettes. Cases of this disease in nonsmokers are very rare; hence, cigarette **smoking** is considered a causative factor. Approximately 40% of the patients have a history of inflammation of a vein (phlebitis), which may play a role in the development of Buerger's disease.

The disease is mainly seen in the legs of affected persons, but may also appear in their arms. Early symptoms include decrease in the blood supply (arterial ischemia) and superficial (near the skin surface) phlebitis. The main symptom is **pain** in the affected areas. Onset of the disease is gradual and first occurs in the feet or hands. Inflammation occurs in small and medium-sized arteries and veins near the surface of the limb. In advanced cases, blood vessels in other parts of the body may be affected. There is a progressive decrease in the blood flow to the affected areas. The pulse in arteries of the feet is weak or undetectable. The lack of blood flow can lead to gangrene, which is decay of tissue due to restricted blood supply. A cold sensitivity in the hands, similar to that seen in Raynaud's disease, can develop. In this case, the hands turn color—white, blue, and then red—when exposed to the cold.

KEY TERMS

Gangrene—A decay of the tissue in a part of the body that experiences restricted blood flow.

Inflammation—A local reaction to irritation, injury, or infection characterized by pain, swelling, redness, and occasional loss of function.

Ischemia—A decrease in the blood supply to an area of the body caused by obstruction or constriction of blood vessels.

Phlebitis—Inflammation of a vein.

Diagnosis

Diagnosis is usually made from the clinical symptoms. Patients frequently complain of numbness, tingling, or burning sensations in the affected area before evidence of vascular inflammation becomes apparent.

Treatment

There is no effective medication or surgery for this disease. Patients must stop smoking to halt further development of the symptoms. **Vasodilators**, drugs that increase the diameter of the blood vessels, can be administered but may not be effective. Exposure of affected areas to heat or cold should be avoided. **Trauma** to the feet and other affected areas should be avoided and infections must be treated promptly.

Prognosis

The disease is progressive in patients who do not stop smoking. Areas with gangrene must be removed surgically.

Prevention

Smoking is the only known causative agent for this disease and should be avoided.

Bulimia nervosa

Definition

Bulimia nervosa is an eating disorder that involves repeated binge eating followed by purging the body of calories to avoid gaining weight. The person who has bulimia has an irrational fear of gaining weight and a distorted **body image**. Bulimia nervosa can have potentially fatal health consequences.

Description

Bulimia is an eating disorder whose main feature is eating an unreasonably large amount of food in a short time, then following this binge by purging the body of calories. Purging is most often done by self-induced **vomiting**, but it can also be done by laxative, enema, or diuretic abuse. Alternately, some people with bulimia do not purge but use extreme exercising and post-binge **fasting** to burn calories. This can lead to serious injury. Non-purging bulimia is sometimes called **exercise** bulimia. Bulimia nervosa is officially recognized as a psychiatric disorder in the *Diagnostic and Statistical Manual for Mental Disorders, Fourth Edition-Text Revision (DSM-IV-TR)*, published by the American Psychiatric Association.

Bulimia nervosa is diagnosed when most of the following conditions are present:

The cuts on the knuckles shown in this photograph are due to the teeth breaking the skin during self-induced vomiting. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

- Repeated episodes of binge eating followed by behavior to compensate for the binge (e.g., purging, fasting, over-exercising). Binge eating is defined as eating a significantly larger amount of food in a limited time than most people typically would eat.
- Binge/purge episodes occur at least twice a week for a period of three or more months.
- The individual feels unable to control or stop an eating binge once it starts and will continue to eat even if uncomfortably full.
- The individual is overly concerned about body weight and shape and puts unreasonable emphasis on physical appearance when evaluating his or her self-worth.
- Bingeing and purging does not occur exclusively during periods of anorexia nervosa.

Many people with bulimia will consume 3,000–10,000 calories in an hour. For example, they will start out intending to eat one slice of cake and end up eating the entire cake. One distinguishing aspect of bulimia is how out of control people with bulimia feel when they are eating. They will eat and eat, continuing even when they feel full and become uncomfortable.

Most people with bulimia recognize that their behavior is not normal; they simply cannot control it. They usually feel ashamed and guilty over their binge/purge habits. As a result, they frequently become secretive about their eating and purging. They may, for example, eat at night after the family has gone to bed or buy food at the grocery store and eat it in the car before going home. Many people with bulimia choose high-fat, high-sugar foods that are easy to eat and easy to regurgitate. They become adept at inducing vomiting, usually by sticking a finger down their throat and triggering the gag reflex. After a while, they can vomit at will. Repeated purging has serious physical and emotional consequences.

Many individuals with bulimia are of normal weight, and a fair number of men who become bulimic were overweight as children. This makes it difficult for family and friends to recognize when someone is suffering from this disorder. People with bulimia may lie about induced vomiting and laxative abuse, although they may complain of symptoms related to their binge/purge cycles and seek medical help for those problems. People with bulimia tend to be more impulsive than people with other **eating disorders**. Lack of impulse control often leads to risky sexual behavior, **anger management** problems, and alcohol and drug abuse.

A subset of people with bulimia also have **anorexia nervosa**. Anorexia nervosa is an eating disorder that involves self-imposed **starvation**. These people often purge after eating only a small or a normal-sized portion of food. Some studies have shown that up to 60% of people with bulimia have a history of anorexia nervosa.

Dieting is usually the trigger that starts a person down the road to bulimia. The future bulimic is very concerned about weight gain and appearance, and may constantly be on a diet. She (most people with bulimia are female) may begin by going on a rigorous low-calorie diet. Unable to stick with the diet, she then eats voraciously, far more than she needs to satisfy her hunger, feels guilty about eating, and then exercises or purges to get rid of the unwanted calories. At first this may happen only occasionally, but gradually these sessions of bingeing and purging become routine and start to intrude on the person's friendships, daily activities, and health. Eventually these practices have serious physical and emotional consequences that need to be addressed by healthcare professionals.

Demographics

Bulimia nervosa is primarily a disorder of industrialized countries where food is abundant and the culture values a thin appearance. Internationally, the rate of bulimia has been increasing since the 1950s. Bulimia is the most common eating disorder in the United States. Overall, about 3% of Americans have bulimia. Of these, 85%–90% are female. The rate is highest among adolescents and college women, averaging 5%–6%. In men, the disorder is more often diagnosed in homosexuals than in heterosexuals. Some experts believe that the number of people diagnosed with bulimia represents only the most severe cases and that many more people have bulimic tendencies, but are successful in hiding their symptoms. In one study, 40% of college women reported isolated incidents of bingeing and purging.

Bulimia affects people from all racial, ethnic, and socioeconomic groups. The disorder usually begins later in life than anorexia nervosa. Most people begin bingeing and purging in their late teens through their twenties. Men tend to start at an older age than women. About 5% of people with bulimia begin the behavior after age 25. Bulimia is uncommon in children under age 14.

Competitive athletes have an increased risk of developing bulimia nervosa, especially in sports where weight is tied to performance and where a low percentage of body fat is highly desirable. Jockeys, wrestlers, bodybuilders, figure skaters, cross-country runners, and gymnasts have higher than average rates of bulimia. People such as actors, models, cheerleaders, and

dancers who are judged mainly on their appearance are also at high risk of developing the disorder. This same group of people is also at higher risk for developing anorexia nervosa. Some people are primarily anorexic and severely restrict their calorie intake while also purging the small amounts they do eat. Others move back and forth between anorexic and bulimic behaviors.

A 2007 report from the National Institute of Mental Health (NIMH) noted that approximately 16% of individuals with bulimia nervosa received treatment for a 12 month period of time, and 43% of individuals with this disorder were receiving lifetime treatment.

Causes and symptoms

Bulimia nervosa is a complex disorder that does not have a single cause. Research suggests that some people have a predisposition toward bulimia and that something triggers the behavior, which then becomes self-reinforcing. Hereditary, biological, psychological, and social factors all appear to play a role.

Causes

- Heredity. Twin studies suggest that there is an inherited component to bulimia nervosa, but that it is small. Having a close relative, usually a mother or a sister, with bulimia slightly increases the likelihood of other (usually female) family members developing the disorder. However, when compared to other inherited diseases or even to anorexia nervosa, the genetic contribution to developing this disorder appears less important than many other factors. Family history of depression, alcoholism, and obesity also increase the risk of developing bulimia.
- Biological factors. There is some evidence that bulimia is linked to low levels of serotonin in the brain. Serotonin is a neurotransmitter. One of its functions is to help regulate the feeling of fullness or satiety that tells a person to stop eating. Neurotransmitters are also involved in other mental disorders, such as depression, that often occur with bulimia. Other research suggests that people with bulimia may have abnormal levels of leptin, a protein that helps regulate weight by telling the body to take in less food. Research in this area is relatively new, and the findings are still unclear.
- Psychological factors. Certain personality types appear to be more vulnerable to developing bulimia. People with bulimia tend to have poor impulse control. They are aware that their behavior is abnormal. After a binge/purge session, they may feel ashamed and vow never to repeat the cycle, but the next time they wish to eat and purge, they are unable to control the impulse. Major depression, obsessive-compulsive disorder, and anxiety disorders are more common among individuals who are bulimic.
- Social factors. The families of people who develop bulimia are more likely to have members who have problems with alcoholism, depression, and obesity. These families also tend to have a high level of open conflict and disordered, unpredictable lives. Often something stressful or upsetting triggers the urge to diet stringently and then begin binge/purge behaviors. This may be as simple as a family member teasing about the person's weight, nagging about eating junk food, commenting on how clothes fit, or comparing the person unfavorably to someone who is thin. Life events such as moving, starting a new school, and breaking up with a boyfriend or girlfriend can also trigger binge/purge behavior. Overlaying the family situation is the false but unrelenting media message that thin is "good" and fat is "bad."

Signs and symptoms

Binge/purge cycles have physical consequences, including:

- teeth damaged from repeated exposure to stomach acid from vomiting; eroded tooth enamel
- swollen salivary glands; sores in mouth and throat
- dehydration
- sores or calluses on knuckles or hands from using them to induce vomiting
- electrolyte imbalances revealed by laboratory tests
- dry skin
- fatigue
- irregular or absent menstrual cycles in women
- weight, heart rate, and blood pressure may be normal

Diagnosis

Diagnosis is based on several factors, including a patient history, **physical examination**, the results of laboratory tests, and a mental status evaluation. A patient history is less helpful in diagnosing bulimia than in diagnosing many diseases because many people with bulimia lie about their bingeing and purging and their use of **laxatives**, **enemas**, and medications. The patient may, however, complain about related symptoms such as **fatigue** or feeling bloated. Many people with bulimia are likely to express extreme concern about their weight during the examination.

A physical examination begins with weight and blood pressure and moves through the body looking for the signs listed above. Based on the physical exam

WWW.BOOKBAZ.IR

and patient history, the physician may order laboratory tests. In general, these tests will include a **complete blood count** (CBC), **urinalysis**, and blood chemistries (to determine electrolyte levels). People suspected of extreme exercising may need to have x rays to look for damage to bones, such as **stressfractures**.

Several different evaluations can be used to examine a person's mental state. A doctor or mental health professional will assess the individual's thoughts and feelings about themselves, their body, their relationships with others, and their risk for self-harm.

Treatment

Treatment choices depend on the degree to which the bulimic behavior has resulted in physical damage and whether the person is a danger to him or herself. Hospital inpatient care may be needed to correct severe electrolyte imbalances that result from repeated vomiting and laxative abuse. Electrolyte imbalances can result in heart irregularities and other potentially fatal complications. Most people with bulimia do not require hospitalization. The rate of hospitalization is much lower than that for people with anorexia nervosa because many people with bulimia maintain a normal weight.

Day treatment or partial hospitalization, where the patient goes every day to an extensive treatment program, provides structured mealtimes, **nutrition** education, intensive therapy, medical monitoring, and supervision. If day treatment fails, the patient may need to be hospitalized or enter a full-time residential treatment facility.

Outpatient treatment provides medical supervision, nutrition counseling, self-help strategies, and **psychotherapy**. Self-help groups receive mixed reviews from healthcare professionals who work with people with bulimia. Some groups offer constructive support in stopping the binge/purge cycle, while others tend to reinforce the behavior.

Drug therapy helps many people with bulimia. **Selective serotonin reuptake inhibitors** (SSRIs) such as fluoxetine (Prozac) and sertraline (Zoloft) have been approved by the United States Food and Drug Administration (FDA) for treatment of bulimia. These medications increase serotonin levels in the brain and are thought to affect the body's sense of fullness. They are used whether or not the patient shows signs of depression. Drug treatment should always be supplemented with psychotherapy.

Other drugs are being explored for use in the treatment of bulimia. Individuals with bulimia interested in entering a clinical trial at no cost can find a list and description of clinical trials currently enrolling volunteers at http://www.clinicaltrials.gov.

Nutrition and dietary concerns

A dietitian is part of the team needed to successfully treat bulimia. These professionals usually perform a dietary review along with nutritional counseling so that the recovering bulimic can plan healthy meals and develop a healthy relationship with food.

Therapy

Medical intervention helps alleviate the immediate physical problems associated with bulimia. Medication can help the person with bulimia break the binge/purge cycle. However, drug therapy alone rarely produces recovery. Psychotherapy plays a major role in helping the individual with bulimia recover from the disorder. Several different types of psychotherapy are used depending on the individual's situation. Generally, the goal of psychotherapy is to help individuals change their behavior and develop a healthy attitude toward their body and food.

Some types of psychotherapy have been successful in treating people with bulimia:

- Cognitive behavior therapy (CBT) is designed to confront and then change people's thoughts and feelings about their body and behaviors toward food, but it does not address why those thoughts or feelings exist. Strategies to maintain self-control may be explored. This therapy is relatively short-term. CBT is often the therapy of choice for people with bulimia, and it is often successful at least in the short term.
- Interpersonal therapy is short-term therapy that helps the individual identify specific issues and problems in relationships. The individual may be asked to look back at his or her family history to try to recognize problem areas and work toward resolving them. Interpersonal therapy has about the same rate of success in people with bulimia as CBT.
- Family and/or couples therapy is helpful in dealing with conflict or disorder that may be a factor in triggering binge/purge behavior at home.
- Supportive-expressive therapy or group therapy may be helpful in addition to other types of therapy.

Prognosis

The long-term outlook for recovery from bulimia is mixed. About half of all people with bulimia show

KEY TERMS

Diuretic—A substance that removes water from the body by increasing urine production.

Electrolyte—Ions in the body that participate in metabolic reactions. The major human electrolytes are sodium (Na+), potassium (K+), calcium (Ca 2+), magnesium (Mg2+), chloride (Cl−), phosphate (HPO_4 2−), bicarbonate (HCO_3−), and sulfate (SO_4 2−).

Neurotransmitter—One of a group of chemicals secreted by a nerve cell (neuron) to carry a chemical message to another nerve cell, often as a way of transmitting a nerve impulse. Examples of neurotransmitters are acetylcholine, dopamine, serotonin, and norepinephrine.

Obsessive-compulsive disorder—A psychiatric disorder in which a person is unable to control the desire to repeat the same action over and over.

improvement in controlling their behavior after short-term interpersonal or cognitive behavioral therapy with nutritional counseling and drug therapy. However, after three years, only about one-third are still doing well. Relapses are common, and binge/purge episodes and bulimic behavior often comes and goes for many years. Stress seems to be a major trigger for relapse.

The sooner treatment is sought, the better the chances of recovery. Without professional intervention, recovery is unlikely. Untreated bulimia can lead to death from causes such as rupture of the stomach or esophagus. Associated problems such as substance abuse, depression, **anxiety disorders**, and poor impulse control also contribute to the death rate.

Prevention

Some behaviors to try to help prevent bulimia nervosa from developing include:

- Parents should not obsess about their weight or appearance in front of their children.
- Do not tease children about their body shape or compare them to others.
- Make sure children know that they are loved and accepted.
- Try to eat meals together as a family whenever possible.
- Remind children that the models they see on television and in fashion magazines have extreme, not normal or healthy, bodies.
- Do not put children on a diet unless advised by a pediatrician.
- Block children from visiting pro-bulimia websites. These are sites where people with bulimia give advice on techniques and support each other's distorted body image.
- If a child is a competitive athlete, get to know the coach and the coach's attitude toward weight.

If parents suspect that their child has an eating disorder, they should not wait to intervene and get professional help. The sooner the disorder is recognized, the easier it is to treat.

Relapses happen to many people with bulimia. People who are recovering from bulimia can help prevent themselves from relapsing by doing the following:

- never dieting and planning healthy meals instead
- eating with other people and not alone
- staying in treatment and keeping therapy appointments
- monitoring negative and practicing positive self-talk
- spending time doing something enjoyable every day
- getting at least seven hours of sleep each night
- spending time each day with family and friends

Bundle branch block

Definition

Bundle branch block (BBB) is a disruption in the normal flow of electrical pulses that drive the heart beat.

Description

Bundle branch block belongs to a group of heart problems called intraventricular conduction defects (IVCD). There are two bundle branches, right and left. The right bundle carries nerve impulses that cause contraction of the right ventricle (the lower chamber of the heart) and the left bundle carries nerve impulses that cause contraction of the left ventricle. The two bundles initially are together at a junction called the bundle of His. Nerve impulses come through the sinus node of the heart to the bundle of His and then move into the right and left bundle branches. Bundle branch block is a slowing or interruption of nerve impulses. A problem may exist in any of the three bundles.

Patients with BBB are generally without symptoms unless the disease is severe enough to cause a complete infranodal A-V block and very slow heart rate. In patients with right bundle branch block (RBBB), the nerve impulse is conducted slowly or not at all. The right ventricle finally receives the impulse through muscle-to-muscle spread, outside the regular nerve pathway. This mechanism of impulse transmission is slow and results in a delayed contraction of the right ventricle. There are several types of left bundle branch block (LBBB), each producing its own characteristic mechanism of failure. In each case, the nerve impulse is blocked or delayed. Patients with LBBB may have left ventricular disease or **cardiomyopathy**.

Causes and symptoms

Left bundle branch block usually happens as a consequence of other diseases such as arteriosclerosis, **rheumatic fever**, **congenital heart disease**, **myocarditis**, myocardial infarction, metastatic heart tumors, or other invasions of the heart tissue. Right bundle branch block happens less often from underlying **heart disease**.

Diagnosis

Detection of BBB usually takes place during a normal **physical examination**. The block shows up as a widening of the second heart sound. Confirmation of BBB is obtained by electrocardiogram (ECG). The pattern seen in the electrocardiogram indicates pulses in a heartbeat and their duration. A QRS duration of

KEY TERMS

Electrocardiogram—The pattern of the heart's electrical impulses that indicates the order and condition of the heart's components.

QRS—A pattern seen in an electrocardiogram that indicates the pulses in a heartbeat and their duration. Variations from a normal QRS pattern indicate heart disease.

greater than 110 milliseconds is a diagnostic indication of BBB. There is a unique ECG pattern for blocks in each of the three bundles.

Treatment

There is no specific therapy for BBB. Patients are usually treated for associated heart diseases.

Prognosis

The prognosis of blockage in any of the three bundle branches depends on the prognosis of the associated heart disease. The associated diseases determine the outcome of the patient's health. Occasionally, disruptions in bundle branches lead to complete infranodal A-V block, a more serious blockage of nerve impulses. Approximately 2% of patients with BBB develop infranodal A-V blockage and these patients often require artificial **pacemakers**.

Bunion

Definition

A bunion is an abnormal enlargement of the joint (the first metatarsophalangeal joint, or MTPJ) at the base of the great or big toe (hallux). It is caused by inflammation and usually results from chronic irritation and pressure from poorly fitting footwear.

Description

A displacement of two major bones of the foot (hallux valgus) causes bunions, although not everyone with this displacement will develop the joint swelling and bone overgrowth that characterize a bunion. One of the bones involved is called the first metatarsal bone. This bone is long and slender, with the big toe attached on one end and the other end connected to foot bones closer to the ankle. This foot bone is displaced in the direction of the four other metatarsals connected with the toes. The other bone involved is the big toe itself, which is displaced toward the smaller toes. As the big toe continues to move toward the smaller toes, it may become displaced under or over the second toe. The displacement of these two foot bones causes a projection of bone on the inside portion of the forefoot. The skin over this projection often becomes inflamed from rubbing against the shoe, and a callus may form.

The joint contains a small sac (bursa) filled with fluid that cushions the bones and helps the joint to move smoothly. When a bunion forms, this sac becomes inflamed and thickened. The swelling in the joint causes additional **pain** and pressure in the toe.

Causes and symptoms

Bunions may form as a result of abnormal motion of the foot during walking or running. One common example of an abnormal movement is an excessive amount of **stress** placed upon the inside of the foot. This leads to friction and irritation of the involved structures. Age has also been noted as a factor in developing bunions, in part because the underlying bone displacement worsens over time unless corrective measures are taken.

Woman's right foot with bunion on big toe. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

KEY TERMS

Orthopedics—A medical specialty concerned with treating diseases, injuries, and malformations of the bones and supporting structures, such as tendons, ligaments, and muscles.

Orthotic—A device or brace to control, correct, or compensate for a bone deformity.

Podiatry—A medical specialty concerned with treating diseases, injuries, and malformations of the feet.

Wearing improperly fitting shoes, especially those with a narrow toe box and excessive heel height, often causes the formation of a bunion. This forefoot deformity is seen more often in women than men. The higher frequency in females may be related to the strong link between footwear fashion and bunions. In fact, in a recent survey of more than 350 women, nearly 90% wore shoes that were at least one size too small or too narrow.

Because genetic factors can predispose people to the hallux valgus bone displacement, a strong family history of bunions can increase the likelihood of developing this foot disorder. Various arthritic conditions and several genetic and neuromuscular diseases, such as **Down syndrome** and **Marfan syndrome**, cause muscle imbalances that can create bunions from displacement of the first metatarsal and big toe. Other possible causes of bunions are leg-length discrepancies, with the bunion present on the longer leg, and **trauma** occurring to the joint of the big toe.

Symptoms of bunions include the common signs of inflammation such as redness, swelling, and pain. The discomfort is primarily located along the inside of the foot just behind the big toe. Because of friction, a callus may develop over the bunion. If an overlapping of the toes is allowed, additional rubbing and pain occurs. Inflammation of this area causes a decrease in motion with associated discomfort in the joint between the big toe and the first metatarsal. If allowed to worsen, the skin over the bunion may break down and cause an ulcer, which also presents a problem of potential infection. (Foot **ulcers** can be particularly dangerous for people with diabetes, who may have trouble feeling the ulcer forming and healing if it becomes infected.)

Diagnosis

A thorough medical history and physical exam by a physician is always necessary for the proper diagnosis of bunions and other foot conditions. X rays can help confirm the diagnosis by showing the bone displacement, joint swelling, and, in some cases, the overgrowth of bone that characterizes bunions. Doctors will also consider the possibility that the joint pain is caused by or complicated by arthritis (which causes destruction of the cartilage of the joint), **gout** (which causes the accumulation of uric acid crystals in the joint), tiny **fractures** of a bone in the foot (stress fractures), or infection and may order additional tests to rule out these possibilities.

Treatment

Conservative

The first step in treating a bunion is to remove as much pressure from the area as possible. People with bunions should wear shoes that have enough room in the toe box to accommodate the bunion and avoid high-heeled shoes and tight-fitting socks or stockings. Dressings and pads help protect the bunion from additional shoe pressure. The application of splints or customized shoe inserts (orthotics) to correct the alignment of the big toe joint is effective for many bunions. Most patients are instructed to rest or choose exercises that put less stress on their feet, at least until the misalignment is corrected. In some cases, physicians also use steroid injections with local anesthetic around the bunion to reduce inflammation.

Surgery

If conservative treatment is not successful, surgical removal of the bunion may be necessary to correct the deformity. This procedure is called a bunionectomy, and there are many variations on the operation, which is usually performed by a surgeon who specializes in treating bone conditions (orthopedics) or by one who specializes in treating the foot (podiatry). Surgeons consider the angle of the bone misalignment, the condition of the bursa, and the strength of the bones when they choose which procedure to use. Most bunionectomies involve the removal of a section of bone and the insertion of pins to rejoin the bone. Sometimes the surgeons may move ligaments (which connect bone to bone in the joint) or tendons (which connect bone to muscle) in order to realign the bones. After this procedure, the bones and other tissues are held in place while they heal by compression dressings or a short cast. The individual must refrain from vigorous **exercise** for six weeks.

Alternatives

Deep friction massage techniques by a physical or massage therapist can be helpful to increase circulation, reduce inflammation, and prevent soft tissue buildup.

Physical therapy also provides useful approaches such as **ultrasound** to help retard or reverse the formation of the bunion. Various taping techniques can be useful to realign the toe and decrease friction and rubbing that may be present. The homeopathic tissue salt *Calcarea phosphorica* can be useful in balancing the bone formation/remodeling.

Prognosis

Often modifications in footwear allow a good prognosis without surgery. If surgery is necessary, complete healing without complications requires approximately four to six weeks. Even after surgery corrects the bone misalignment, patients are usually instructed to continue wearing low-heeled, roomy shoes to prevent the bunion from reforming.

Prevention

Prevention begins with proper foot wear. Shoes with a wide and deep toe box are best. High-heeled shoes should not be worn for long periods of time. If a bunion is present and becomes inflamed, the foot should be elevated with the application of an ice pack over the painful area for not more than 20 minutes every other hour. If pain and swelling continue, a podiatrist or physician should be contacted.

Burns

Definition

Burns are injuries to tissues caused by heat, friction, electricity, radiation, or chemicals.

Classification of burns

First-degree burn	The burned area is painful. The outer skin is reddened. Slight swelling is present.
Second-degree burn	The burned area is painful. Deeper layers of skin (the dermis) are affected. Blisters may form. The area may have a wet, shiny appearance because of exposed tissue.
Third-degree burn	The burned area is insensitive due to the destruction of nerve endings. Skin is destroyed. Muscle tissue and bone underneath may be damaged. The area may be charred, white, or grayish in color.

(Table by PreMediaGlobal. © Cengage Learning®.)

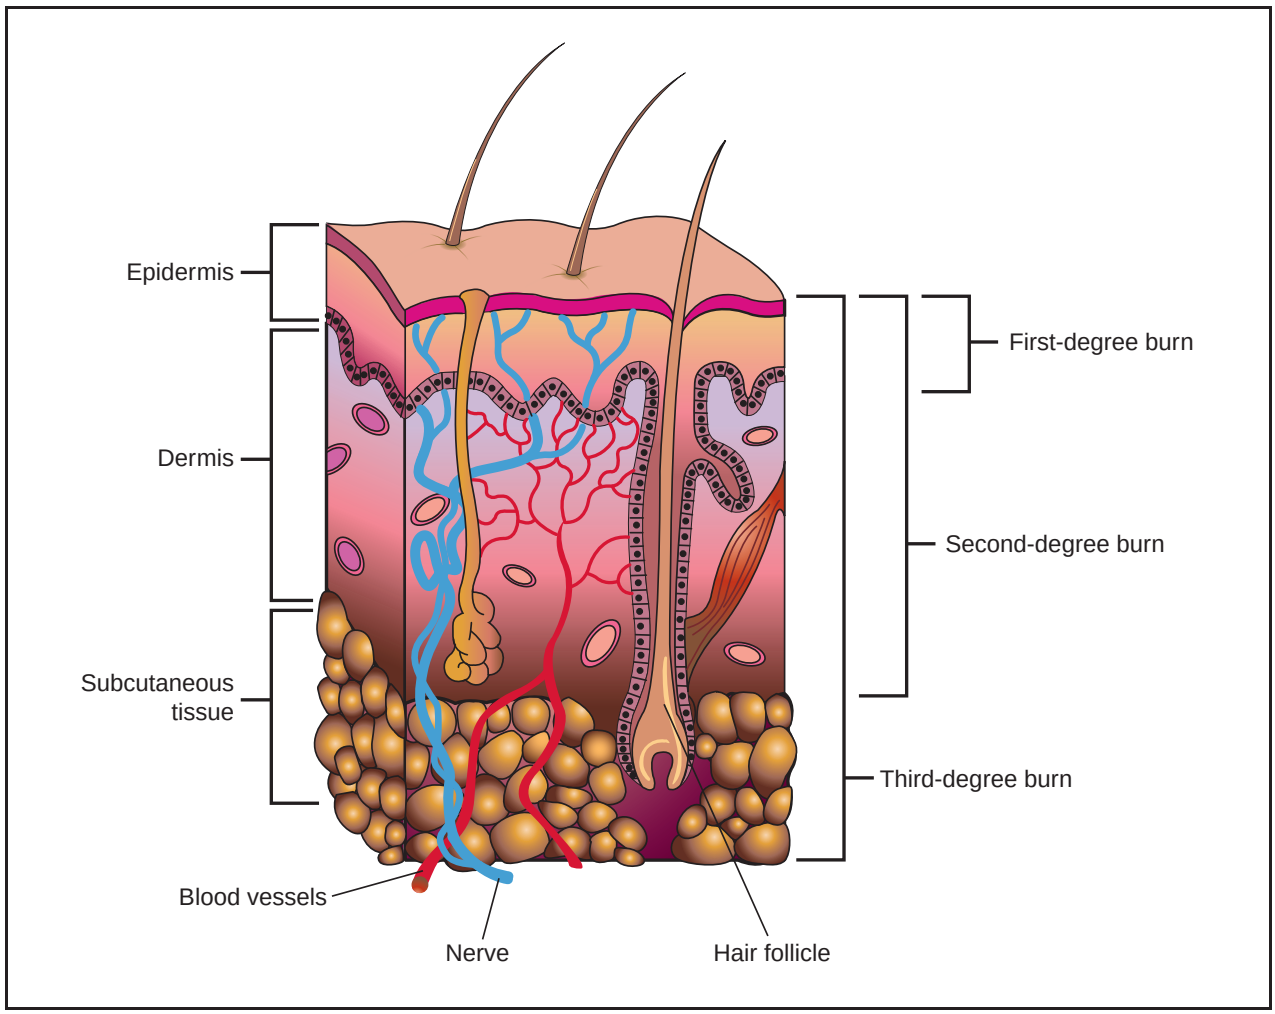
Description

Burns are characterized by degree, based on the severity of the tissue damage. A first-degree burn causes redness and swelling in the outermost layers of skin (epidermis). A second-degree burn involves redness, swelling, and blistering, and the damage may extend beneath the epidermis to deeper layers of skin (dermis). A third-degree burn, also called a full-thickness burn, destroys the entire depth of skin, causing significant scarring. Damage also may extend to the underlying fat, muscle, or bone.

The severity of the burn is also judged by the amount of body surface area (BSA) involved. Healthcare workers use the "rule of nines" to determine the percentage of BSA affected in patients more than nine years old: each arm with its hand is 9% of BSA; each leg with its foot is 18%; the front of the torso is 18%; the back of the torso, including the buttocks, is 18%; the head and neck are 9%; and the genital area (perineum) is 1%. This rule cannot be applied to a young child's body proportions, so BSA is estimated using the palm of the patient's hand as a measure of 1% area.

The severity of the burn will determine not only the type of treatment, but also where the burn patient should receive treatment. Minor burns may be treated at home or in a doctor's office. These are defined as first- or second-degree burns covering less than 15% of an adult's body or less than 10% of a child's body, or a third-degree burn on less than 2% BSA. Moderate burns should be treated at a hospital. These are defined as first- or second-degree burns covering 15%–25% of an adult's body or 10%–20% of a child's body, or a third-degree burn on 2%–10% BSA. Critical, or major, burns are the most serious and should be treated in a specialized burn unit of a hospital. These are defined as first- or second-degree burns covering more than 25%

WWW.BOOKBAZ.IR



There are three classifications of burns: first-degree, second-degree, and third-degree. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

of an adult's body or more than 20% of a child's body, or a third-degree burn on more than 10% BSA. In addition, burns involving the hands, feet, face, eyes, ears, or genitals are considered critical. Other factors influence the level of treatment needed, including associated injuries such as bone **fractures** and **smoke inhalation**, presence of a chronic disease, or a history of being abused. Also, children and the elderly are more vulnerable to complications from burn injuries and require more intensive care.

Causes and symptoms

Burns may be caused by even a brief encounter with heat greater than 120°F (49°C). The source of this heat may be the sun (causing a **sunburn**), hot liquids, steam, fire, electricity, friction (causing rug burns and rope burns), and chemicals (causing a caustic burn upon contact).

Signs of a burn are localized redness, swelling, and **pain**. A severe burn will also blister. The skin may also peel, appear white or charred, and feel numb. A burn may trigger a **headache** and **fever**. Extensive burns may induce **shock**, the symptoms of which are faintness, weakness, rapid pulse and breathing, pale and clammy skin, and bluish lips and fingernails.

Diagnosis

A physician will diagnose a burn based upon visual examination, and will also ask the patient or family members questions to determine the best treatment. He or she may also check for smoke inhalation, **carbon monoxide poisoning**, cyanide **poisoning**, other event-related **trauma**, or, if suspected, further evidence of **child abuse**.

KEY TERMS

Debridement—The surgical removal of dead tissue.

Dermis—The basal layer of skin, which contains blood and lymphatic vessels, nerves, glands, and hair follicles.

Epidermis—The outer portion of skin, made up of four or five superficial layers.

Shock—An abnormal condition resulting from low blood volume due to hemorrhage or dehydration. Signs of shock include rapid pulse and breathing, and cool, moist, pale skin.

Treatment

Burn treatment consists of relieving pain, preventing infection, and maintaining body fluids, electrolytes, and calorie intake while the body heals. Treatment of chemical or electrical burns is slightly different from the treatment of thermal burns but the objectives are the same.

Thermal burn treatment

The first act of thermal burn treatment is to stop the burning process. This may be accomplished by letting cool water run over the burned area or by soaking it in cool (not cold) water. Ice should never be applied to the burn. Cool (not cold) wet compresses may provide some pain relief when applied to small areas of first- and second-degree burns. Butter, shortening, or similar salve should never be applied to the burn since it prevents heat from escaping and drives the burning process deeper into the skin.

If the burn is minor, it may be cleaned gently with soap and water. Blisters should not be broken. If the skin of the burned area is unbroken and it is not likely to be further irritated by pressure or friction, the burn should be left exposed to the air to promote healing. If the skin is broken or apt to be disturbed, the burned area should be coated lightly with an antibacterial ointment and covered with a sterile bandage. **Aspirin**, **acetaminophen** (Tylenol), or ibuprofen (Advil) may be taken to ease pain and relieve inflammation. A doctor should be consulted if these signs of infection appear: increased warmth, redness, pain, or swelling; pus or similar drainage from the wound; swollen lymph nodes; or red streaks spreading away from the burn.

In situations where a person has received moderate or critical burns, lifesaving measures take precedence over burn treatment and emergency medical assistance must be called. A person with serious burns may stop breathing, and artificial respiration (also called mouth-to-mouth resuscitation or rescue breathing) should be administered immediately. Also, a person with burns covering more than 12% BSA is likely to go into shock; this condition may be prevented by laying the person flat and elevating the feet about 12 in (30 cm). Burned arms and hands should also be raised higher than the person's heart.

In rescues, a blanket may be used to smother any flames as the person is removed from danger. The person whose clothing is on fire should "stop, drop, and roll" or be assisted in lying flat on the ground and rolling to put out the fire. Afterwards, only burnt clothing that comes off easily should be removed; any clothing embedded in the burn should not be disturbed. Removing any smoldering apparel and covering the person with a light, cool, wet cloth, such as a sheet but not a blanket or towel, will stop the burning process.

At the hospital, the staff will provide further medical treatment. A tube to aid breathing may be inserted if the patient's airways or lungs have been damaged, as can happen during an explosion or a fire in a enclosed space. Also, because burns dramatically deplete the body of fluids, replacement fluids are administered intravenously. The patient is also given **antibiotics** intravenously to prevent infection, and he or she may also receive a **tetanus** shot, depending on his or her immunization history. Once the burned area is cleaned and treated with antibiotic cream or ointment, it is covered in sterile bandages, which are changed two to three times a day. Surgical removal of dead tissue (**debridement**) also takes place. As the burns heal, thick, taut scabs (eschar) form, which the doctor may have to cut to improve blood flow to the more elastic healthy tissue beneath. The patient will also undergo physical and **occupational therapy** to keep the burned areas from becoming inflexible and to minimize scarring.

In cases where the skin has been so damaged that it cannot properly heal, a skin graft is usually performed. A skin graft involves taking a piece of skin from an unburned portion of the patient's body (autograft) and transplanting it to the burned area. When doctors cannot immediately use the patient's own skin, a temporary graft is performed using the skin of a human donor (allograft), either alive or dead, or the skin of an animal (xenograft), usually that of a pig.

The burn victim also may be placed in a hyperbaric chamber, if one is available. In a hyperbaric chamber (which can be a specialized room or enclosed space), the patient is exposed to pure oxygen under high pressure, which can aid in healing. However, for this therapy to be effective, the patient must be placed in a chamber within 24 hours of being burned.

ARTIFICIAL SKIN

(Daniel HulshizerAP Photo)

The first artificial skin was invented by Ioannis Yannas (b. 1935) and John Burke (1922–2011). Artificial skin is something of a misnomer, as it is not actually a full skin that can replace a patient's skin but rather a fine mesh that when placed on the body where skin is absent allows the body to regrow its own skin.

For hundreds of years, a serious burn on a large portion of a person's body was nearly a death sentence. Very few individuals ever recovered, and the older the patient and the more area of the body burned, the less chance of survival. The widely accepted method for treating burns left the burned skin on the body, allowing the skin to slough off naturally. John Burke, a surgeon and Harvard Medical School professor decided there was a better way.

Burke believed that leaving the burned skin on patients actually increased the likelihood of infection, a very common cause of death among these individuals. The burned skin provides no barrier against disease and allows fluid from the body to evaporate quickly, leading to a high risk of dehydration. Burke believed that by removing the burned skin patients would have a better chance at recovery.

Removing burned skin created a problem, however. Something was needed to cover the area that was now left exposed. The first option Burke tried was skin provided by donors. This approach created a serious complication, as burn patients needed strong immunosuppressant drugs to keep their bodies from rejecting the donor skin. These drugs reduced their ability to fight infection. So Burke determined to find a synthetic option. It would have to be a flexible and easily synthesized barrier against agents of infection. In 1969, Burke brought the problem to Ioannis Yannas, a professor at the Massachusetts Institute of Technology who specialized in mechanical engineering involving fibers and polymers.

Over nearly two decades, the men worked together to create and test a synthetic skin, which eventually was named Integra® dermal regeneration template. The synthetic skin is a very fine, two layered mesh. The lower layer contains collagen from cows, covered with glycosaminoglycan, a type of sugar molecule. This lower layer encourages the dermis layer of the skin to regrow, and the matrix of collagen provides a structure to support the regenerating dermis. The top layer of synthetic skin is made of very thin silicon. This top layer plays a role similar to the epidermis, slowing evaporation and providing a barrier against infection.

Once the dermis has grown back, the silicon layer is peeled off. In some cases, the patient's own epidermal cells spontaneously regenerate the area. In other cases, the area is seeded with healthy epidermal cells from elsewhere on the body. After the epidermis successfully grows back, the new skin is healthy and similar to normal skin. The new skin, however, does not have hair follicles or sweat glands. Thanks to artificial skin, the prognosis for burn victims greatly improved, and thousands of people every year recovered successfully with new, healthy skin.

Chemical burn treatment

Burns from liquid chemicals must be rinsed with cool water for at least 15 minutes to stop the burning process. Any burn to the eye must be similarly flushed with water. In cases of burns from dry chemicals such as lime, the powder should be completely brushed away before the area is washed. Any clothing that may have absorbed the chemical should be removed. The burn should then be loosely covered with a sterile gauze pad and the person taken to the hospital for further treatment. A physician may be able to neutralize the offending chemical with another before treating the burn like a thermal burn of similar severity.

Electrical burn treatment

Before electrical burns are treated at the site of the accident, the power source must be disconnected if possible and the victim moved away from it to keep the person giving aid from being electrocuted. Lifesaving measures again take priority over burn

treatment, so breathing must be checked and assisted if necessary. Electrical burns should be loosely covered with sterile gauze pads and the person taken to the hospital for further treatment.

Alternatives

In addition to the excellent treatment of burns provided by traditional medicine, some alternative approaches may be helpful as well, though major burns should always be treated by a medical practitioner. The homeopathic remedies *Cantharis* and *Causticum* can assist in burn healing. A number of botanical remedies, applied topically, can also help burns heal. These include aloe (*Aloe barbadensis*), oil of St. John's wort (*Hypericum perforatum*), calendula (*Calendula officinalis*), comfrey (*Symphytum officinale*), and tea tree oil (*Melaleuca* spp.). Supplementing the diet with vitamin C, **vitamin E**, and zinc also is beneficial for wound healing.

Prognosis

The prognosis is dependent upon the degree of the burn, the amount of body surface covered, whether critical body parts were affected, any additional injuries or complications like infection, and the promptness of medical treatment. Minor burns may heal in 5 to 10 days with no scarring. Moderate burns may heal in 10–14 days and may leave scarring. Critical or major burns take more than 14 days to heal and will leave significant scarring. Scar tissue may limit mobility and functionality, but **physical therapy** may overcome these limitations. In some cases, additional surgery may be advisable to remove scar tissue and restore appearance.

Prevention

Burns are commonly received in residential fires. Properly placed and working smoke detectors in combination with rapid evacuation plans will minimize a person's exposure to smoke and flames in the event of a fire. Children must be taught never to play with matches, lighters, fireworks, gasoline, and cleaning fluids.

Burns by scalding with hot water or other liquids may be prevented by setting the water heater thermostat no higher than 120°F (49°C), checking the temperature of bath water before getting into the tub, and turning pot handles on the stove out of the reach of children. Care should be used when removing covers from pans of steaming foods and when uncovering or opening foods heated in a microwave oven.

Thermal burns are often received from electrical appliances. Care should be exercised around stoves, space heaters, irons, and curling irons.

Sunburns may be avoided by the liberal use of a sunscreen containing either an opaque active ingredient such as zinc oxide or titanium dioxide or a nonopaque active ingredient such as PABA (para-aminobenzoic acid) or benzophenone. Hats, loose clothing, and umbrellas also provide protection, especially between 10 a.m. and 3 p.m. when the most damaging ultraviolet rays are present in direct sunlight.

Electrical burns may be prevented by covering unused electrical outlets with safety plugs and keeping electrical cords away from infants and toddlers who might chew on them. Persons should also seek shelter indoors during a thunderstorm to avoid being struck by lightning.

Chemical burns may be prevented by wearing protective clothing, including gloves and eyeshields. Chemical agents should always be used according to the manufacturer's instructions and properly stored when not in use.

Bursitis

Definition

Bursitis is the painful inflammation of the bursa, a padlike sac found in areas subject to friction. Bursae cushion the movement between the bones, tendons and muscles near the joints. Bursitis is most often caused by repetitive movement and is known by several common names including weaver's bottom, clergyman's knee, and miner's elbow, depending on the affected individual's occupation and area of injury.

Description

There are over 150 bursae in the human body. Usually bursae are present from birth, but they may form in

WWW.BOOKBAZ.IR

KEY TERMS

Arthritis—Inflammation of a joint that may lead to changes in the joint's structure. It causes pain and swelling. Rheumatoid arthritis is a chronic disease that leads to crippling deformities.

Diabetes mellitus—A metabolic disease caused by a deficiency of insulin, which is essential to process carbohydrates in the body.

Gout—A hereditary metabolic disease that is a form of arthritis and causes inflammation of the joints. It is more common in men.

Inflammation—Tedness, swelling, heat, and pain, which comprise a reaction of tissue to injury.

Kinesiology—The science or study of movement.

response to repeated pressure. Each sac contains a small amount of *synovial fluid,* a clear liquid that acts as a lubricant. Inflammation causes **pain** on movement. The most common site for bursitis to occur is the shoulder (subdeltoid), but it also is seen in the elbows (olecranon), hips (trochanteric), knees, heels (Achilles), and toes. The affected area may be referred to as "frozen," because movement is so limited. In the knee there are four bursae, and all can become inflamed with overuse.

Causes and symptoms

The most common cause of bursitis is repeated physical activity, but it can flare up for no known reason. It can also be caused by **trauma**, **rheumatoid arthritis**, **gout**, and acute or chronic infection.

Pain and tenderness are common symptoms. If the affected joint is close to the skin, as with the shoulder, knee, elbow, or Achilles tendon, swelling and redness are seen and the area may feel warm to the touch. The bursae around the hip joint are deeper, and swelling is not obvious. Movement may be limited and is painful. In the shoulder, it may be difficult to raise the arm out from the side of the body. Putting on a jacket or combing the hair becomes a troublesome activity.

In acute bursitis symptoms appear suddenly; with chronic bursitis, pain, tenderness, and limited movement reappear after **exercise** or strain.

Diagnosis

When a patient has pain in a joint, a careful **physical examination** is needed to determine what type of movement is affected and if there is any swelling present. Bursitis will not show up on x rays, although sometimes there are also **calcium** deposits in the joint that can be seen. Inserting a thin needle into the affected bursa and removing (aspirating) some of the synovial fluid for examination can confirm the diagnosis. In most cases, the fluid will not be clear. It can be tested for the presence of microorganisms, which would indicate an infection, and crystals, which could indicate gout. In instances where the diagnosis is difficult, a local anesthetic (a drug that numbs the area) is injected into the painful spot. If the discomfort stops temporarily, then bursitis is probably the correct diagnosis.

Treatment

Conservative treatment of bursitis is usually effective. The application of heat, rest, and **immobilization** of the affected joint area is the first step. A sling can be used for a shoulder injury; a cane is helpful for hip problems. The patient can take **nonsteroidal anti-inflammatory drugs** (NSAIDs) like **aspirin**, ibuprofin, and naproxen. They can be obtained without a prescription and relieve the pain and inflammation. Once the pain decreases, exercises of the affected area can begin. If the nearby muscles have become weak because of the disease or prolonged immobility, then exercises to build strength and improve movement are best. A doctor or physical therapist can prescribe an effective regimen.

If the bursitis is related to an inflammatory condition like arthritis or gout, then management of that disease is needed to control the bursitis.

When bursitis does not respond to conservative treatment, an injection into the joint of a long-acting corticosteroid preparation, like prednisone, can bring immediate and lasting relief. A corticosteroid is a hormonal substance that is the most effective drug for reducing inflammation. The drug is mixed with a local anesthetic and works on the joint within five minutes. Usually one injection is all that is needed.

Surgery to remove the damaged bursa may be performed in extreme cases.

If the bursitis is caused by an infection, then additional treatment is needed. *Septic* bursitis is caused by the presence of a pus-forming organism, usually *staphylococcus aureus*. This is confirmed by examining a sample of the fluid in the bursa and requires treatment with **antibiotics** taken by mouth, injected into a muscle or into a vein (intravenously). The bursa will also need to be drained by needle two or three times over the first week of treatment. When a patient has such a serious infection, there may be underlying causes. There could be undiscovered diabetes, or an

inefficient immune system caused by human **immunodeficiency** virus infection (HIV).

Alternatives

Alternative treatments take into consideration the role of diet in causing bursitis. The faulty use of calcium by the body, magnesium deficiency, and **food allergies** may have a role. Diet changes and vitamin supplements may be helpful. The use of herbs, homeopathy, **aromatherapy**, and **hydrotherapy** can help relieve symptoms. Ginger is useful in reducing inflammation. **Acupuncture** has been proven effective in treating hip and shoulder pain caused by bursitis and other conditions. Other therapies that deal effectively with musculoskeletal problems (relating to the muscles and skeleton), may also be helpful, such as body work, **magnetic field therapy**, **naturopathic medicine**, **chiropractic**, and **applied kinesiology**.

Prognosis

Bursitis usually responds well to treatment, but it may develop into a chronic condition if the underlying cause is not corrected.

Prevention

Aggravating factors should be eliminated to prevent bursitis. Overexercising or the repetition of a movement that triggers the condition should be avoided. Doing exercises to strengthen the muscles around the joint will also help. When doing repetitive tasks, frequent breaks should be taken and the activity should be alternated with others using different parts of the body. To cushion the joints, it is a good idea to use cushioned chairs when sitting and foam kneeling pads for the knees. Leaning on the elbows, kneeling, or sitting on a hard surface for a long period of time should be avoided. Not wearing high heels can help prevent bursitis in the heel, as can changing to new running shoes as soon as the old ones are worn out.

Bypass surgery *see* **Coronary artery bypass graft surgery**

Byssinosis

Definition

Byssinosis is a chronic, asthma-like narrowing of the airways. Also called brown lung disease, byssinosis results from inhaling particles of cotton, flax, hemp, or jute.

Description

Although inhaling cotton dust was identified as a source of respiratory disease more than 300 years ago, byssinosis has been recognized as an occupational hazard for textile workers for less than 50 years. More than 800,000 workers in the cotton, flax, and rope-making industries are exposed in the workplace to airborne particles that can cause byssinosis. Only workers in mills that manufacture yarn, thread, or fabric have a significant risk of dying of this disease.

In the United States, byssinosis is almost completely limited to workers who handle unprocessed cotton. More than 35,000 textile workers have been disabled by byssinosis and 183 died between 1979 and 1992. Most of the people whose deaths were due to byssinosis lived in the textile-producing regions of North and South Carolina.

Causes and symptoms

As many as 25% of workers with byssinosis have symptoms that continue or recur throughout the workweek. More severe breathing problems seem to result both from exposure to high levels of dust and from longer dust exposure. Workers who also smoke cigarettes suffer the most severe impairment.

Diagnosis

Tests that detect decreasing lung capacity during the workday are used to diagnose byssinosis. Obstructive patterns are likely in patients who have had recurrent symptoms for more than 10 years.

Treatment

Therapy for early-stage byssinosis focuses on reversing airway narrowing. **Antihistamines** may be prescribed to reduce tightness in the chest. **Bronchodilators** (drugs used to relax breathing passages and improve air flow) may be used with an inhaler or taken in tablet form. Reducing exposure is essential. Any worker who has symptoms of byssinosis or who

WWW.BOOKBAZ.IR

KEY TERMS

Wheeze—A whistling sound made by the flow of high-velocity air through narrowed airways. Wheezing is a symptom of several respiratory diseases, including byssinosis and asthma.

has trouble breathing should transfer to a less-contaminated area.

Prognosis

Smoking, impaired lung function, and a history of respiratory allergy increase a textile worker's risk of developing byssinosis. Prolonged exposure makes patients wheeze more often and can cause chronic **bronchitis**. It does not lead to permanently disabling lung disease.

Prevention

Eliminating exposure to textile dust is the surest way to prevent byssinosis. Using exhaust hoods, improving ventilation, and employing wetting procedures are very successful methods of controlling dust levels to prevent byssinosis. Protective equipment required during certain procedures also prevents exposure to levels of contamination that exceed the current United States standard for cotton dust exposure.

Caffeine

Definition

Caffeine is a mild alkaloid stimulant made by some plants. It is found in coffee beans, tea leaves, and cocoa beans; added to soft drinks, **energy drinks**, and energy bars; and sold in capsules and tablets as a dietary supplement.

Purpose

Caffeine is a mild stimulant. It is used to temporarily relieve **fatigue** and increase mental alertness. Caffeine is added to some antihistamine drugs to help counteract the sleepiness they may cause. It is also added to over-the-counter **headache** remedies (e.g., Excedrin) and **migraine headache** drugs to enhance their painkilling effects. Under medical supervision, citrated caffeine (a prescription drug) is used to treat breathing problems in premature infants.

Description

Caffeine, from the Italian word *cafée*, meaning coffee, is naturally made by about 60 plants. The most familiar of these are coffee leaves and beans, tea leaves, kola nuts, yerba mate, guarana berries, and cacao (the source of chocolate). In plants, caffeine is a pesticide. Insects eating plants that contain caffeine become disabled or die.

Humans have eaten plants containing caffeine for thousands of years; first chewing the seeds and leaves, and later boiling them and drinking the resulting liquid. Coffee, a major source of caffeine, was introduced to Europe from the Middle East in the seventeenth century and rapidly became a popular drink. Coffee houses began appearing in London in the mid-1600s. A German chemist purified caffeine in 1819. Today, besides being found naturally in coffee, tea, and chocolate, it is added to soft drinks, energy drinks and bars, headache remedies, and is sold as a dietary supplement to improve mental and physical functioning.

Caffeine has no nutritional value, but it has these effects on the body:

- increases heart rate
- temporarily increases blood pressure
- relaxes smooth muscle cells in the airways
- releases fatty acids and glycerol in the body for energy use
- easily crosses the blood-brain barrier and changes the level of neurotransmitters in the brain
- passes into breast milk

It used to be believed that caffeine acted as a diuretic, which is any substance that increases urine output. Research has since found that these effects are very mild, and that the diuretic effect is seen only when caffeine is consumed in large doses (500 to 600 milligrams [mg], or up to seven cups of coffee per day). This means that moderate consumption of coffee and other caffeinated beverages does not cause **dehydration**.

Caffeine is absorbed in the stomach. Its effects are noticeable in about 15 minutes and usually last several hours. However, there is a huge variation among people both in their sensitivity to caffeine and in how long it stays in their bodies. Although the average time it takes half a dose of caffeine to be eliminated from the body is three to four hours, this time may extend to six hours in women taking **oral contraceptives**, and be

WWW.BOOKBAZ.IR

much longer in pregnant women and in people with liver damage.

Many well-designed, well-documented studies show that caffeine makes people more alert, improves short-term memory, enhances the ability to concentrate, increases the individual's capacity for physical work, and speeds up reaction time. In habitual caffeine drinkers, caffeine achieves this by preventing the detrimental effects of withdrawal. It does not boost functioning to above normal levels. All of these effects are temporary. Caffeine does not replace the need for rest or sleep.

Caffeine is on the U.S. Food and Drug Administration's (FDA) list of foods generally recognized as safe (GRAS). In moderate amounts, caffeine does not appear to be harmful to humans, although it is poisonous to dogs, horses, and some birds. "Moderate" generally means consumption in the range of 300–400 mg or 3–4 cups of coffee daily. Caffeine has not been shown to cause **birth defects** and is considered safe in reasonable amounts during **pregnancy**. The March of Dimes Foundation recommends that pregnant women limit their caffeine intake to 200 mg per day, roughly the amount in one 12-ounce cup of coffee. Women experiencing difficulty becoming pregnant may wish to completely eliminate caffeine from their diet.

By law, caffeine must be listed as an ingredient on food labels, but the amount of caffeine per serving is not required to be disclosed. Since caffeine is added to so many products, it is difficult to measure the amount of caffeine in an individual's diet. Caffeine content of coffees and teas varies depending on where the plants were grown and how the beverages are prepared.

Benefits

Research is conflicting, but there seem to be some benefits to regular caffeine consumption. A 2012 study published in the *Journal of Alzheimer's Disease* found that drinking roughly three cups of coffee per day could help prevent or delay the onset of Alzheimer's disease. Other studies have linked similar amounts of caffeine consumption to improved memory and long-term cognition. A study of more than 50,000 women, published in the September 2011 issue of the *Archives of Internal Medicine*, found that women who drank at least four cups of coffee per day had a significantly lower rate (0.2%) of depression than women drinking fewer than one cup per week or even one cup per day (1.3% and 1.8%, respectively). Other benefits associated with moderate-to-high caffeine consumption include decreased risk of **skin cancer** (three cups per day), improved athletic performance (one to five cups), and longer life expectancy (six cups).

Tea is another good source of caffeine. Though most caffeinated teas have less caffeine per cup than coffee, drinking tea is associated with myriad benefits, due to tea's antioxidant properties.

Precautions

People vary in their sensitivity to caffeine based on their weight, age, medications they may be taking, personal biology, and habitual intake. Individuals should be alert to how much caffeine they consume during a day and how it makes them feel, then adjust their intake accordingly. All of caffeine's effects are temporary, and a "crash" is likely to occur after a dose of caffeine wears off.

Caffeine stays in the system of pregnant women and people with liver damage longer than normal. These people should closely monitor their caffeine intake.

Caffeine passes into breast milk and although it may have no effect on the **breastfeeding** woman, it may make the infant restless, irritable, and less likely to sleep. Recommendations for breastfeeding women vary from one to three cups of coffee per day; if the infant seems to react to the caffeine, the mother should reduce her intake.

Athletes should be aware that the International Olympic Committee tests for caffeine levels over 12 mg/mL of urine. This level could be reached by drinking four large cups of coffee.

Caffeine has increasingly been added to alcoholic beverages. The FDA views this practice as unsafe and in 2010 ordered several manufacturers of caffeinated alcoholic beverages to cease production. Some beverages are still available, but the effects of combining caffeine and alcohol have not been sufficiently tested, and the full extent of possible adverse effects is not yet known.

Interactions

Caffeine appears to enhance the effectiveness of over-the-counter headache and migraine remedies. Some of these medications contain a mixture of caffeine and painkiller. People with a high sensitivity to caffeine or those trying to reduce or monitor their intake (e.g., pregnant women) should read the labels carefully.

People taking diuretic medication (water pills) may see increased urine output because caffeine is a weak diuretic.

Complications

Although caffeine in moderate amounts poses no major health risks, the body quickly develops tolerance to the effects of caffeine, along with a mild physical and psychological dependency. For example, tolerance to caffeine-related sleep disruption disappears in about a week among people who drink three to four cups of coffee daily. The amount of caffeine it takes to reach this state is highly variable.

Discontinuing caffeine among regular users can cause withdrawal symptoms. These can include headaches (very common), irritability, nausea, fatigue, sleepiness, inability to concentrate, and mild depression. Caffeine withdrawal symptoms begin 12–24 hours after caffeine is stopped. Withdrawal symptoms peak at around 48 hours, and can last up to five days. Tapering caffeine use, for example cutting down on caffeine by the equivalent of half a cup of coffee (about 50 mg) a day, minimizes or eliminates withdrawal symptoms.

People who consume more than 500 mg of caffeine a day—equivalent to about five cups of coffee—may develop a condition called caffeinism, though the threshold varies among individuals. Caffeinism produces unpleasant sensations, some of which are similar to withdrawal symptoms. Symptoms of caffeine overuse include restlessness, irritability, nervousness, **anxiety**, muscle twitching, headaches, inability to fall asleep, and a racing heart. Severe overuse of caffeine can cause a number of related disorders, including:

- Caffeine intoxication—usually the result of taking caffeine pills (e.g., NoDoz), this condition causes mental changes, rambling thoughts and speech, irregular heartbeat, and other symptoms associated with overuse. In severe cases death can result from ventricular fibrillation (unsynchronized contractions of the ventricle of the heart).
- Caffeine-induced anxiety disorder—severe anxiety that interferes with daily social interactions and occurs after caffeine intoxication or heavy long-term use of caffeine.
- Caffeine-induced sleep disorder—an inability to sleep that is so great it requires medical/psychiatric attention and occurs after prolonged caffeine consumption.
- Non-specific caffeine-induced disorder—disorders not listed that are attributable to either acute or long-term caffeine consumption.

Concerns

Children get most of their caffeine from soft drinks. Parents should choose soft drinks that contain little or no caffeine or replace soft drinks with water, fruit juice, or low-fat milk. Adolescents are increasingly using energy drinks and energy bars containing caffeine. In addition, adolescence is the time when many people start drinking coffee. Parents should educate their children about the effects of caffeine and encourage them to monitor their caffeine consumption from all sources.

Accidental overdose from caffeine pills can be fatal. Caffeine tablets, like all drugs, should be kept out of reach of children. Children who accidentally eat caffeine pills need immediate medical attention from a physician.

KEY TERMS

Alkaloid—An organic compound found in plants; chemically it is a base and usually contains at least one nitrogen atom.

Blood-brain barrier—A specialized, semi-permeable layer of cells around the blood vessels in the brain that controls which substances can leave the circulatory system and enter the brain.

Diuretic—A substance that removes water from the body by increasing urine production.

Neurotransmitter—One of a group of chemicals secreted by a nerve cell (neuron) to carry a chemical message to another nerve cell, often as a way of transmitting a nerve impulse. Examples of neurotransmitters include acetylcholine, dopamine, serotonin, and norepinephrine.

Tolerance—Adjustment of the body to a drug so that it takes more and more to produce the same physiological or psychological effect, or adjustment to a drug so that side effects are diminished.

Calcium

Definition

Calcium (chemical symbol: Ca) is the most abundant mineral in the body. About 99% of calcium in the body is in bones and teeth. The remaining 1% is in blood and soft tissue. Calcium in body fluids is an electrolyte with a charge of 2+. Humans must meet their need for calcium through diet.

Purpose

Calcium is essential for:

- building and maintaining strong bones and teeth
- muscle contraction
- blood vessel contraction and relaxation
- nerve impulse transmission
- regulating fluid balance in the body

Description

Most calcium in the body is stored in bones and teeth. Here it combines with phosphate to form strong, stable crystals. The remaining 1% is dissolved in body fluids and much of it occurs in the form of positively charged calcium ions, Ca^{2+}. In the body, these electrically charged particles are called electrolytes. Calcium and other electrolytes are not distributed evenly throughout the body. Dissolved calcium is found mainly in the fluid outside cells (extracellular fluid). Metabolic events cause the movement of calcium across cell membranes resulting in muscle contraction, nerve impulse transmission, and various chemical reactions. The cell then uses energy to restore the balance of calcium between the inside and outside of the cell membrane, so that the event can be repeated.

To remain healthy, the amount of calcium dissolved in body fluids must stay within a very narrow

Calcium

Age	Recommended dietary allowance (mg)	Tolerable upper intake level (mg)
Children 0–6 mos.	200 (AI)	1,000
Children 7–12 mos.	260 (AI)	1,500
Children 1–3 yrs.	700	2,500
Children 4–8 yrs.	1,000	2,500
Children 9–13 yrs.	1,300	3,000
Adolescents 14–18 yrs.	1,300	3,000
Adults 19-50 yrs.	1,000	2,500
Adults 50> yrs.	1,000	2,000
Pregnant women 18≤ yrs.	1,300	3,000
Pregnant women 19≥ yrs.	1,000	2,500
Breastfeeding women 18≤ yrs.	1,300	3,000
Breastfeeding women 19≥ yrs.	1,000	3,000

Food	Calcium (mg)
Yogurt, plain, 8 oz.	415

(Table by PreMediaGlobal. © Cengage Learning®.)

range. Bone acts like a calcium bank. It is constantly being broken down by cells called osteoclasts and built up again by cells called osteoblasts. This process is called bone remodeling, and it continues throughout an individual's life. When excess calcium is present in the blood, osteoblasts deposit calcium into bones. When too little calcium is in the blood, osteoblasts dissolve calcium from bones and move it into the blood. This process is controlled by parathyroid hormones (PTH) secreted by the parathyroid glands. The parathyroid glands are extremely sensitive to the level of calcium in the blood, and in a healthy individual they are able to maintain the concentration of calcium ions within very close limits.

Normal calcium requirements

The United States Institute of Medicine (IOM) of the National Academy of Sciences has developed values called dietary reference intakes (DRIs) for many **vitamins** and **minerals**. The DRIs consist of three sets of numbers. The recommended dietary allowance (RDA) defines the average daily amount of a nutrient needed to meet the health needs of 97%–98% of the population. The adequate intake (AI) is an estimate set when there is not enough information to determine an RDA. The tolerable upper intake level (UL) is the average maximum amount that can be taken daily without risking negative side effects. The DRIs are calculated for children, adult men, adult women, pregnant women, and lactating women. The Food and Nutrition Board (FNB) of the IOM regularly reviews and, as necessary, revises the recommended RDAs, AIs, and ULs for all categories of men and women, boys and girls.

The current RDAs for calcium, as established by the FNB, are as follows:

- children 0–6 months: 200 mg (AI)
- children 7–12 months: 260 mg (AI)
- children 1–3 years: 700 mg
- children 4–8 years: 1,000 mg
- adolescents 9–18 years: 1,300 mg
- males 19–70 years: 1,000 mg
- females 19–50 years: 1,000 mg
- females 51 and older: 1,200 mg
- males 71 and older: 1,200 mg
- pregnant and lactating women 18 years and younger: 1,300 mg
- pregnant and lactating women over age 18: 1,000 mg

The U.S. RDAs tend to be higher than international recommended values. For example, the requirement for adults in the United Kingdom is 700 mg per day. Recommended dietary intakes in Australia are similar for adults but less for children (500 mg for children aged 1–3, 700 mg for children 4–8, and 1,000 mg for children 9–11).

Sources of calcium

In the United States, dairy products—milk, yogurt, and cheese—are the main sources of dietary calcium. Low-fat dairy products, such as skim milk or reduced-fat cheese, contain about the same amount of calcium as whole milk products. Other sources of calcium include canned fish with bones, dark green leafy vegetables, and tofu made with calcium sulfate. Other types of tofu do not contain significant amounts

WWW.BOOKBAZ.IR

of calcium. Processed foods such as orange juice, breakfast cereal, instant breakfast drinks, and bread are often fortified with calcium. This fact will be indicated on the label.

The following list gives the approximate calcium content for some common foods:

- bok choy, 1/2 cup cooked: 61 mg
- bread, whole wheat, 1 slice: 20 mg
- breakfast cereal, fortified, 1 cup: 100–1,000 mg
- cheddar cheese, 1.5 ounces: 305 mg
- milk, any type, 1 cup (8 ounces): 300 mg
- mozzarella cheese, 1.5 ounces: 370 mg
- orange juice, fortified, 6 ounces: 200–260 mg
- pinto or red beans, cooked, 1/2 cup: 43 mg
- salmon with bones, canned, 3 ounces: 181 mg
- sardines with bones, canned in oil, 3 ounces: 324 mg
- spinach, cooked, 1/2 cup: 120 mg
- tofu, firm, made with calcium sulfate, 1/2 cup: 204 mg
- white beans, cooked, 1/2 cup: 113 mg
- yogurt, plain, 8 ounces: 415 mg
- yogurt, with fruit, 8 ounces: 245–380 mg

It is important to note that although a food may contain a significant amount of calcium, there is a difference between the total calcium content of a food and the amount that is available to the body (bioavailability). Other components present in foods may inhibit the body's access to those foods' calcium supplies. For example, oxalic acid, which is present in spinach, limits the absorption of calcium. So, although spinach is relatively high in calcium, not all of that calcium is absorbed by the body. Kale, on the other hand, contains less calcium than spinach but its calcium content is more easily absorbed in the body.

Although experts recommend that people meet as many of their vitamin and mineral needs as possible through diet, it is difficult for many people to get enough calcium from food alone. This is especially true for vegans, who eat no dairy products, adolescent girls who are very calorie conscious and tend to avoid milk and replace it with diet sodas, and people with **lactose intolerance** who cannot easily digest dairy products. Pregnant women and older individuals may also have a hard time eating enough to meet their calcium needs. People who do not get enough calcium through diet can benefit from taking a dietary supplement containing calcium.

Calcium supplements are available over-the-counter. The most common supplements supply calcium in the form of calcium carbonate or calcium citrate. Calcium carbonate is usually the most economical calcium supplement. People who are taking medications to reduce stomach acid may absorb calcium citrate more easily. Some supplements combine calcium and **vitamin D** because vitamin D helps the body absorb calcium. No calcium supplement contains enough calcium to meet the entire daily adequate intake, because the pill would be too large to swallow. In addition, the body absorbs calcium best in doses of 500 mg or less. People who need more than 500 mg of supplemental calcium should divide the dose in half to be taken in the morning and evening.

Calcium deficiency

Calcium deficiency, called **hypocalcemia**, can occur because of inadequate calcium intake, excess calcium excretion by the kidneys (usually caused by kidney damage), the inability to adequately absorb calcium, or interactions between calcium and some prescription drugs. People at highest risk of calcium deficiency are teenagers, women past the age of **menopause**, individuals who are lactose intolerant, vegans, and people with kidney (renal) damage.

Calcium deficiency rarely shows up in blood tests because calcium is withdrawn from the bones to maintain blood levels of calcium. The bones then become less dense, weaker, and more likely to break. This condition is called **osteoporosis**, and it is most noticeable in the elderly, who have a high rate of broken bones resulting from falls. Osteoporosis is a part of **aging**, but eating a healthy diet high in calcium, getting adequate vitamin D, and doing weight-bearing exercises regularly can delay its onset. Severe calcium deficiency is usually caused by a medical condition rather than inadequate calcium intake. It causes symptoms such as **muscle cramps**, tingling in the fingers, lethargy, convulsions, and heart rhythm abnormalities, and may even result in death. These symptoms can also be caused by many other diseases.

Calcium excess

Calcium excess is called **hypercalcemia**. It usually results from poor kidney function (renal failure) or from a malignant cancer tumor. It can also be caused by very large supplemental doses of vitamin D. Very rarely is hypercalcemia caused by too much calcium from food or dietary supplements. High levels of calcium interfere with the absorption of other minerals such as iron, zinc, magnesium, and phosphorous. People with hypercalcemia usually have multiple medical problems and are under the supervision of a physician.

Precautions

People of all ages, races, and genders need to be alert to getting enough calcium in their diet. Building strong, dense bones begins in childhood and adolescence, even though the results cannot be seen until old age. People who are at an especially high risk of low dietary calcium intake should investigate taking a calcium supplement.

Interactions

Absorption of calcium is affected by several conditions.

- Age. Infants absorb as much as 60% of the calcium in their digestive system. This decreases to 15–20% in adulthood, and even less in old age.
- Pregnancy. Pregnancy increases the efficiency of calcium absorption in the intestines to meet the demands of fetal development.
- Amount of calcium consumed. The more calcium consumed at one time, the less efficient absorption becomes. Calcium from supplements should be spaced out during the day for maximum absorption.
- Vitamin D. The presence of vitamin D improves calcium absorption. Vitamin D deficiency can worsen calcium deficiency.
- Plant products. Phytic acid, found in beans, and oxalic acid, found in spinach and leafy greens, decrease the amount of calcium absorbed from those foods but do not affect the absorption of calcium from other foods present at the same time in the intestines. Fiber also reduces calcium absorption.

Prescription medications can also affect or be affected by the absorption of calcium. These include:

- digoxin
- fluoroquinolones
- levothyroxine
- tetracycline antibiotics
- anticonvulsants
- thiazide-type diuretics
- glucocorticoids
- mineral oil
- stimulant laxatives
- antacids

People taking these drugs should check with their healthcare provider or pharmacist about potential adjustments in their medications or calcium intake.

Complications

Some studies have found an increased risk of **heart attack** in people taking calcium supplements. An 11-year study published in the June 2012 issue of the journal *Heart* saw an 86% increase in heart attack risk among a group of almost 24,000 German adults. Previous studies done on post-menopausal women taking calcium supplements, with or without vitamin D supplementation, have found similar results. Calcium and vitamin D supplements are often recommended to older women to reduce the risk of osteoporosis and bone **fractures**, which increases with age and after menopause. The U.S. Preventive Services Task Force, an independent group that works in cooperation with the Agency for Healthcare Research and Quality, recommended in mid-2012 that older adults not take such supplements, due to a lack of supporting evidence. Although further research is needed, it is always advisable to obtain the majority of nutrients from foods and not supplements.

Calcium supplements may cause gas, nausea, and abdominal discomfort. Taking the supplement with meals, taking smaller doses spread out over the day, or changing the type of supplement usually solves this problem.

Parental concerns

Building strong bones starts in childhood, and parents should be aware of how much calcium their child needs compared to how much he or she is getting. As children get older they tend to replace milk in their diet with juice, bottled water, and especially carbonated soft drinks. This practice leads to large calcium deficiencies during adolescence. Parents should monitor their child's diet and encourage them to take calcium supplements if they cannot induce their adolescents to eat more dairy products and other calcium-rich food.

Calcium carbonate *see* **Antacids**

Calcium channel blockers

Definition

Calcium channel blockers are medicines that slow the movement of calcium into the cells of the heart and blood vessels. This, in turn, relaxes blood vessels, increases the supply of oxygen-rich blood to the heart, and reduces the heart's workload.

Purpose

Calcium channel blockers are used to treat high blood pressure, to correct abnormal heart rhythms, and to relieve the type of chest **pain** called angina pectoris. Physicians also prescribe calcium channel blockers to treat panic attacks and **bipolar disorder** (manic depressive illness) and to prevent **migraine headache**.

Precautions

Seeing a physician regularly while taking calcium channel blockers is important. The physician will check to make certain the medicine is working as it should and will watch for unwanted side effects. People who have high blood pressure often feel perfectly fine. However, they should continue to see their prescribing physician even when they feel well so that he can keep a close watch on their condition. They should also continue to take their medicine even when they feel fine.

Calcium channel blockers will not cure high blood pressure, but will help to control the condition. To avoid the serious health problems associated with high blood pressure, patients may have to take this type of medication for the rest of their lives. Furthermore, the blockers alone may not be enough. People with high blood pressure may also need to avoid certain foods and keep their weight under control. The health care professional who is treating the condition can offer advice as to what measures may be necessary. Patients being treated for high blood pressure should not change their **diets** without consulting their physicians.

Anyone taking calcium channel blockers for high blood pressure should not take any other prescription or over-the-counter medication without first checking with the prescribing physician, as some of these drugs may increase blood pressure.

Some people feel drowsy or less alert than usual when taking calcium channel blockers. Anyone who takes these drugs should not drive, use machines, or do anything else that might be dangerous until they have found out how the drugs affect them.

People who normally have chest pain when they **exercise** or exert themselves may not have the pain when they are taking calcium channel blockers. This could lead them to be more active than they should be. Anyone taking calcium channel blockers should therefore consult with the prescribing physician concerning how much exercise and activity may be considered safe.

Some people get headaches that last for a short time after taking a dose of this medication. This problem usually goes away during the course of treatment. If it does not, or if the headaches are severe, the prescribing physician should be informed.

Patients taking certain calcium channel blockers may need to check their pulse regularly, as the drugs may slow the pulse too much. If the pulse is too slow, circulation problems may result. The prescribing physician can show patients the correct way to check their pulse.

This type of medication may cause the gums to swell, bleed, or become tender. If this problem occurs, a medical physician or dentist should be consulted. To help prevent the problem, care should be taken when brushing and flossing the teeth. Regular dental checkups and cleanings are also recommended.

Older people may be unusually sensitive to the effects of calcium channel blockers. This may increase the chance of side effects.

Special conditions

People with certain medical conditions or who are taking certain other medicines may develop problems if they also take calcium channel blockers. Before taking these drugs, the prescribing physician should be informed about any of these conditions:

ALLERGIES. Anyone who has had a previous unusual reaction to any calcium channel blocker should let his or her physician know before taking the drugs again. The physician should also be notified about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. The effects of taking calcium channel blockers during **pregnancy** have not been studied in humans. However, in studies of laboratory animals, large doses of these drugs have been reported to cause **birth defects**, **stillbirth**, poor bone growth, and other problems when taken during pregnancy. Women who are pregnant or who may become pregnant should check with their physicians before using these drugs.

BREASTFEEDING. Some calcium channel blockers pass into breast milk, but there have been no reports of problems in nursing babies whose mothers were taking this type of medication. However, women who need to take this medicine and want to breastfeed their babies should check with their physicians.

OTHER MEDICAL CONDITIONS. Calcium channel blockers may worsen heart or blood vessel disorders.

The effects of calcium channel blockers may be greater in people with kidney or **liver disease**, as their bodies are slower to clear the drug from their systems.

Certain calcium channel blockers may also cause problems in people with a history of heart rhythm problems or with depression, Parkinson's disease, or other types of parkinsonism.

USE OF CERTAIN MEDICINES. Taking calcium channel blockers with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

As with most medications, certain side effects are possible and some interactions with other substances may occur.

Side effects

Side effects are not common with this medicine, but some may occur. Minor discomforts, such as **dizziness**, lightheadedness, flushing, **headache**, and nausea, usually go away as the body adjusts to the drug and do not require medical treatment unless they persist or they are bothersome.

WWW.BOOKBAZ.IR

If any of the following side effects occur, the prescribing physician should be notified as soon as possible:

- breathing problems, coughing or wheezing
- irregular, fast, or pounding heartbeat
- slow heartbeat (less than 50 beats per minute)
- skin rash
- swollen ankles, feet, or lower legs

Other side effects may occur. Anyone who has unusual symptoms after taking calcium blockers should contact the prescribing physician.

Interactions

Calcium channel blockers may interact with a number of other medications. When this happens, the effects of one or both of the drugs may change or the risk of side effects may increase. Anyone who takes calcium channel blockers should not take any other prescription or nonprescription (over-the-counter) medicines without first checking with the prescribing physician. Substances that may interact with calcium channel blockers include:

- Diuretics (water pills). This type of medicine may cause low levels of potassium in the body, which may increase the chance of unwanted effects from some calcium channel blockers.
- Beta-blockers, such as atenolol (Tenormin), propranolol (Inderal), and metoprolol (Lopressor), used to treat high blood pressure, angina, and other conditions. Also, eye drop forms of beta blockers, such as timolol (Timoptic), used to treat glaucoma. Taking any of these drugs with calcium channel blockers may increase the effects of both types of medicine and may cause problems if either drug is stopped suddenly.
- Digitalis heart medicines. Taking these medicines with calcium channel blockers may increase the action of the heart medication.
- Medicines used to correct irregular heart rhythms, such as quinidine (Quinidex), disopyramide (Norpace), and procainamide (Procan, Pronestyl). The effects of these drugs may increase if used with calcium channel blockers.
- Anti-seizure medications such as carbamazepine (Tegretol). Calcium channel drugs may increase the effects of these medicines.
- Cyclosporine (Sandimmune), a medicine that suppresses the immune system. Effects may increase if this drug is taken with calcium channel blockers.
- Grapefruit juice may increase the effects of some calcium channel blockers.

This list does not include every drug that may interact with calcium channel blockers. The prescribing physician or pharmacist will advise as to whether combining calcium channel blockers with any other prescription or nonprescription (over-the-counter) medication is appropriate or not.

Description

Calcium channel blockers are available only with a physician's prescription and are sold in tablet, capsule, and injectable forms. Some commonly used calcium channel blockers include amlopidine (Norvasc), diltiazem (Cardizem), isradipine (DynaCirc), nifedipine (Adalat, Procardia), nicardipine (Cardene), and verapamil (Calan, Isoptin, Verelan).

The recommended dosage depends on the type, strength, and form of calcium channel blocker and the condition for which it is prescribed. Correct dosage is determined by the prescribing physician and further information can be obtained from the pharmacist.

Calcium channel blockers should be taken as directed. Larger or more frequent doses should not be taken, nor should doses be missed. This medicine may take several weeks to noticeably lower blood pressure. The patient taking calcium channel blockers should keep taking the medicine, to give it time to work. Once it begins to work and symptoms improve, it should continue to be taken as prescribed.

This medicine should not be discontinued without checking with the prescribing physician. Some conditions may worsen when patients stop taking calcium channel blockers abruptly. The prescribing physician will advise as to how to gradually taper down before stopping the medication completely.

Risks

A report from the European Cardiology Society in 2000 found that patients taking certain calcium channel blockers had a 27% greater risk of **heart attack**, and a 26% greater risk of **heart failure** than patients taking other high blood pressure medicines. However, there are many patients affected by conditions that still make calcium channel blockers the best choice for them. The patient should discuss this issue with the prescribing physician.

Results

The expected result of taking a calcium channel blocker is to either correct abnormal heart rhythms, return blood pressure to normal, or relieve chest pain.

KEY TERMS

Angina pectoris—A feeling of tightness, heaviness, or pain in the chest, caused by a lack of oxygen in the muscular wall of the heart.

Bipolar disorder—A severe mental illness, also known as manic depression, in which a person has extreme mood swings, ranging from a highly excited state—sometimes with a false sense of well–being—to depression.

Migraine—A throbbing headache that usually affects only one side of the head. Nausea, vomiting, increased sensitivity to light, and other symptoms often accompany migraine.

Campylobacteriosis

Definition

Campylobacteriosis refers to infection by the group of bacteria known as *Campylobacter*. The term comes from the Greek word meaning "curved rod" referring to the bacteria's curved shape. The most common disease caused by these organisms is **diarrhea**, which most often affects children and younger adults. *Campylobacter* infections account for a substantial percent of food-borne illness encountered each year.

Description

There are over 15 different subtypes, all of which are curved Gram-negative rods. *C. jeuni* is the subtype that most often causes gastrointestinal disease. However, some species such as *C. fetus* produce disease outside the intestine, particularly in those with altered immune systems, such as people with **AIDS**, cancer, and **liver disease**.

Campylobacter are often found in the intestine of animals raised for food products and pets. Infected animals often have no symptoms. Chickens are the most common source of human infection. It is estimated that 1% of the general population is infected each year.

Causes and symptoms

Improper or incomplete food preparation is the most common way the disease is spread, with poultry accounting for over half the cases. Untreated water and raw milk are also potential sources.

The incubation period after exposure is from one to 10 days. A day or two of mild **fever**, muscle aches, and **headache** occur before intestinal symptoms begin. Diarrhea with or without blood and severe abdominal cramps are the major intestinal symptoms. The severity of symptoms is variable, ranging from only mild fever to **dehydration** and rarely death (mainly in the very young or old). The disease usually lasts about one week, but persists longer in about 20% of cases. At least 10% will have a relapse, and some patients will continue to pass the bacteria for several weeks.

Complications

Dehydration is the most common complication. Especially at the extremes of age, this should be watched for and treated with either Oral Rehydration Solution or intravenous fluid replacement.

Infection may also involve areas outside the intestine. This is unusual, except for infections with *C. fetus*. *C. fetus* infections tend to occur in those

WWW.BOOKBAZ.IR

KEY TERMS

Antibiotic—A medication that is designed to kill or weaken bacteria.

Anti-motility medications—Medications such as loperamide (Imodium), dephenoxylate (Lomotil), or medications containing codeine or narcotics which decrease the ability of the intestine to contract. This can worsen the condition of a patient with dysentery or colitis.

Fluoroquinolones—A relatively new group of antibiotics that have had good success in treating infections with many Gram-negative bacteria. One drawback is that they should not be used in children under 17 years of age, because of possible effect on bone growth.

Food-borne illness—A disease that is transmitted by eating or handling contaminated food.

Gram-negative—Refers to the property of many bacteria that causes them to not take up color with Gram's stain, a method which is used to identify bacteria. Gram-positive bacteria which take up the stain turn purple, while Gram-negative bacteria which do not take up the stain turn red.

Guillain-Barré syndrome—Progressive and usually reversible paralysis or weakness of multiple muscles usually starting in the lower extremities and often ascending to the muscles involved in respiration. The syndrome is due to inflammation and loss of the myelin covering of the nerve fibers, often associated with an acute infection.

Meninges—Outer covering of the spinal cord and brain. Infection is called meningitis, which can lead to damage to the brain or spinal cord and even death.

Oral Rehydration Solution (ORS)—A liquid preparation developed by the World Health Organization that can decrease fluid loss in persons with diarrhea. Originally developed to be prepared with materials available in the home, commercial preparations have recently come into use.

Stool—Passage of fecal material; a bowel movement.

who have diseases of decreased immunity such as AIDS, cancer, etc. This subtype is particularly adapted to protect itself from the body's defenses.

Areas outside the intestine that may be involved are:

- Nervous system involvement either by direct infection of the meninges (outer covering of the spinal cord and brain) or more commonly by producing the Guillain-Barré syndrome (progressive and reversible paralysis or weakness of many muscles). In fact, *Campylobacter* may be responsible for 40% of the reported cases of this syndrome.
- Joint inflammation can occur weeks later (leading to an unusual form of arthritis).
- Infection of vessels and heart valves is a special characteristic of *C. fetus*. Immunocompromised patients may develop repeated episodes of passage of bacteria into the bloodstream from these sites of infection.
- The gallbladder, pancreas, and bone may be affected.

Diagnosis

Campylobacter is only one of many causes of acute diarrhea. Culture (growing the bacteria in the laboratory) of freshly obtained diarrhea fluid is the only way to be certain of the diagnosis.

Treatment

The first aim of treatment is to keep up **nutrition** and avoid dehydration. Medications used to treat diarrhea by decreasing intestinal motility, such as Loperamide or Diphenoxylate are also useful, but should only be used with the advice of a physician. **Antibiotics** are of value, if started within three days of onset of symptoms. They are indicated for those with severe or persistent symptoms. Either an erythromycin type drug or one of the **fluoroquinolones** (such as ciprofloxacin) for five to seven days are the accepted therapies.

Prognosis

Most patients with *Campylobacter* infection rapidly recover without treatment. For certain groups of patients, infection becomes chronic and requires repeated courses of antibiotics.

Prevention

Good hand washing technique as well as proper preparation and cooking of food is the best way to prevent infection.

Cancer

Definition

Cancer is not just one disease, but a large group of over 100 diseases. Its two main characteristics are uncontrolled growth of the cells in the human body and the ability of these cells to migrate from the original site and spread to distant sites. If the spread is not controlled, cancer can result in death.

Demographics

About 1.665 million Americans, 855,000 males and 810,000 females, will be diagnosed with cancer in 2014. This figure does not, however, include the 2.8 million cases of skin cancer diagnosed in the United States each year, because skin cancers are not reported to cancer registries. One out of every four deaths in the United States is from cancer; cancer is the second most common cause of death in North America, exceeded only by heart disease. More than 585,700 people in the United States, 310,000 males and 275,000 females, are anticipated to die of cancer in 2014, which equates to more than 1,600 deaths from cancer per day. About 176,000 of these 585,000 cases are caused by smoking or the use of smokeless tobacco. Overall, however, cancer death rates for both men and women have decreased since 2004.

Because the occurrence of cancer increases as individuals age, most of the cases are diagnosed in adults, middle-aged or older. Seventy-seven percent of all cancers as of 2014 are diagnosed in people who are older than 55 years of age. The probability of an American male developing an invasive cancer or dying from cancer in his lifetime is slightly less than 1 in 2; for American females the probability is slightly more than 1 in 3. The most common cancers in the United States as of 2014 are skin cancer, lung cancer, colon cancer, breast cancer (in women), and prostate cancer (in men). In addition, cancer of the kidneys, ovaries, uterus, pancreas, bladder, rectum, and blood and lymph node cancer (leukemias and lymphomas) are also included among the 12 major cancers that affect most Americans.

Cancer incidence and mortality in the United States, 2014[1]

Type of cancer	Number of new diagnoses	Number of deaths
Breast cancer	235,030	40,430
Cervical cancer[2]	12, 360	4,020
Colorectal cancer	136,830	50,301
Lung cancer	224,210	159,260
Non-Hodgkin lymphoma	70,800	18,990
Ovarian cancer	21,980	14,270
Prostate cancer	233,000	29,480
Skin cancer, melanoma	76,100	9,710
Testicular cancer	8,820	380

[1]Numbers are estimates
[2]Invasive

SOURCE: American Cancer Society, Cancer Facts & Figures, 2014. Atlanta: American Cancer Society (2014).

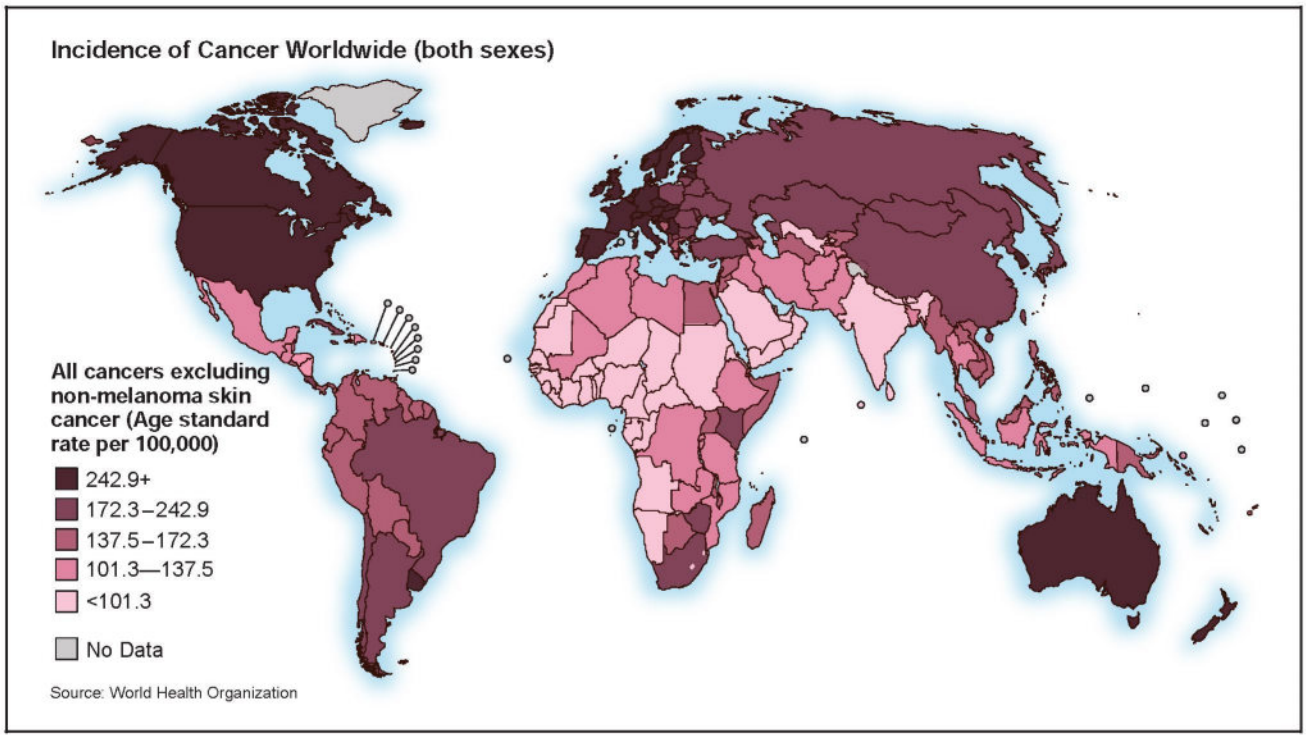
(Table by PreMediaGlobal. © Cengage Learning®.)

Although most cancer occurs in adults, in the United States cancer is still responsible for more deaths in young people under age 20 than any other disease; after accidents, it is the largest single cause of death in children between the ages of 5 and 14. One child in every 408 will be diagnosed with cancer before age 15, and one in every 285 will be diagnosed with cancer before his or her twentieth birthday. Each year, about 10,500 new cases of cancer are diagnosed in children compared to 1.6 million new cases annually in adults. In 2014, about 10,450 new cases and 1,350 cancer deaths are expected to occur among children in the United States. Cancers in children, however, are different from those diagnosed in adults; the most common types of pediatric cancers are leukemia (26%); cancers of the brain and central nervous system (18%); and lymphoma (14%). In general, children respond better to cancer treatment than adults do. Advances in treatment have resulted in better outcomes and increased long-term survival rates for children. Eighty percent of children newly diagnosed with cancer now live at least five years compared to about 60% in the mid-1970s; death rates for pediatric cancers have declined steadily from 1975 to 2014. In terms of race and ethnicity, Caucasian and Hispanic children and adolescents have the highest rates of pediatric cancers, while African American children have lower incidence rates. Death rates, however, are similar for all three groups due to lower survival rates in African Americans.

Description

Cancer by definition is a disease of the genes. A gene is a small part of DNA, which is the master

WWW.BOOKBAZ.IR



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

molecule of the cell. Genes make proteins, which are the ultimate workhorses of the cells. These proteins allow the body to carry out all the many processes that permit an individual to function—to breathe, think, and move.

Throughout people's lives, the cells in their bodies are growing, dividing, and replacing themselves. Many genes produce proteins that are involved in controlling the processes of cell growth and division. An alteration (mutation) in the DNA molecule can disrupt the genes and produce faulty proteins. These changes cause the cell to become abnormal and lose its restraints on growth. The abnormal cell begins to divide uncontrollably and eventually forms a new growth known as a tumor or neoplasm (medical term for cancer, meaning "new growth").

In a healthy individual, the immune system can recognize the neoplastic cells and destroy them before they get a chance to divide. However, some mutant cells may escape immune detection and survive to become tumors or cancers.

Tumors are of two types, benign or malignant. A benign tumor is not considered cancer. It is typically slow-growing, does not spread or invade surrounding tissue, and once it is removed, does not usually recur. A malignant tumor, by contrast, is cancer. It invades surrounding tissue and spreads to other parts of the body. If the cancer cells have spread to the surrounding tissues, even after the malignant tumor is removed, it generally recurs.

A majority of cancers are caused by changes in the cell's DNA because of damage to the environment. Environmental factors that are responsible for causing the initial mutation in the DNA are called carcinogens, of which there are many types.

Some cancers have a genetic or inherited basis. In other words, individuals can inherit faulty DNA from a parent, which could predispose the person to getting cancer. While there is scientific evidence that both factors (environmental and genetic) play a role, less than 10% of all cancers are strictly linked to hereditary factors. Cancers that are known to have a hereditary link are breast cancer, cancer of the male breast, colon cancer, ovarian cancer, uterine cancer, and some types of melanoma. Besides genes, certain physiological traits could be inherited and could contribute to cancers. For example, inheriting fair skin makes a person more likely to develop skin cancer, but only if that person also has prolonged exposure to intensive sunlight.

There are several different types of cancers:

- Carcinomas are cancers that arise in the epithelium (the layer of cells covering the body's surface and

lining the internal organs and various glands). Ninety percent of human cancers fall into this category. Carcinomas can be subdivided into two types: adenocarcinomas (those that develop in an organ or a gland) and squamous cell carcinomas (those that originate in the skin).

- Melanomas also originate in the skin, usually in the pigment cells (melanocytes).
- Sarcomas are cancers of the supporting tissues of the body, such as bone, muscle, and blood vessels.
- Cancers of the blood and lymph glands are called leukemias and lymphomas, respectively.
- Gliomas are cancers of the nerve tissue.

Risk factors

The major risk factors for cancer are related to age, tobacco and alcohol use, dietary factors, sexual and reproductive behavior, exposure to infectious agents, family history, occupation, and environmental factors including pollution.

Causes and symptoms

According to estimates of the American Cancer Society (ACS), approximately 40% of cancer deaths in 2014 were anticipated to be due to tobacco and excessive alcohol use. An additional one-third of the deaths were expected to be related to being overweight, being obese, lacking physical activity, and having poor nutrition. Many of the 3 million skin cancers diagnosed in 2013 were believed to be a direct result of over-exposure to ultraviolet light from the sun's rays.

Tobacco

Eighty to 90% of lung cancer cases occur in smokers. Smoking has also been shown to be a contributory factor in cancers of the upper respiratory tract, esophagus, larynx, bladder, pancreas, and probably liver, stomach, breast, and kidney as well. In the 2000s, scientists also confirmed that secondhand smoke (or passive smoking) can increase one's risk of developing cancer.

Alcohol

Excessive consumption of alcohol is a risk factor in certain cancers, such as liver cancer. Alcohol, in combination with tobacco, significantly increases the chances that an individual will develop mouth, pharynx, larynx, and esophageal cancers.

Common pathogens and associated cancers

Causative agent	Type(s) of cancer
Viruses	
Epstein-Barr virus	Burkitt's lymphoma
Hepatitis B	Liver cancer
Hepatitis C	Liver cancer
Human immunodeficiency virus (HIV)	Kaposi's sarcoma, lymphoma
Papillomaviruses	Cervical cancer
Bacteria	
Helicobacter pylori	Stomach cancer, lymphomas

(Table by PreMediaGlobal. © Cengage Learning®.)

Diet

Between a quarter and a third of all cancers in the United States are due to diet, coupled with lack of exercise. Excessive intake of fat leading to obesity has been associated with cancers of the breast, colon, rectum, pancreas, prostate, gall bladder, ovaries, and uterus.

Sexual and reproductive behavior

The human papillomavirus (HPV), which is sexually transmitted, has been shown to cause cancer of the cervix and is a risk factor for cancer of the penis. Having multiple sexual partners and becoming sexually active at an early age have been shown to increase one's chances of contracting HPV. In addition, it has also been shown that women who do not have children or have children later in life have an increased risk of both ovarian and breast cancer.

Infectious agents

Between 1985 and 2005, scientists obtained evidence to show that approximately 15% of the world's cancer deaths can be traced to viruses, bacteria, or parasites. The most common cancer-causing pathogens and the cancers associated with them were shown previously in table form.

Family history

Certain cancers such as breast, colon, ovarian, and uterine cancer recur generation after generation in some families. A few cancers, such as the eye cancer retinoblastoma, some types of melanoma, a type of colon cancer, and a type of breast cancer known as early-onset breast cancer, have been shown to be linked to

WWW.BOOKBAZ.IR

KEY TERMS

Adjuvant therapy—Treatment involving radiation, chemotherapy (drug treatment), hormone therapy, biotherapeutics, or a combination of any of these given after the primary treatment in order to rid the body of residual microscopic cancer.

Benign—Mild, nonmalignant. Recovery is favorable with treatment.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Bone marrow—Spongy material that fills the inner cavities of the bones. The progenitors of all the blood cells are produced in this bone marrow.

Carcinogen—Any substance capable of causing cancer by mutating the cell's DNA.

Chemotherapy—Treatment with certain anticancer drugs.

Debulking—The surgical removal of part of a cancerous tumor that cannot be completely excised, in order to improve the effectiveness of radiation therapy or chemotherapy.

Epithelium—The layer of cells covering the body's surface and lining the internal organs and various glands.

Hormone therapy—Treatment of cancer by inhibiting the production of hormones such as testosterone and estrogen.

Immunotherapy—Treatment of cancer by stimulating the body's immune defense system.

certain genes that can be tracked within a family. It is therefore possible that inheriting particular genes makes a person susceptible to certain cancers.

Occupational hazards

There is evidence to show that certain occupational hazards account for 4% of all cancer deaths. For example, asbestos workers have an increased incidence of lung cancer. Similarly, a higher likelihood of getting bladder cancer is associated with dye, rubber, and gas workers; skin and lung cancer with smelters, gold miners, and arsenic workers; leukemia with glue and varnish workers; liver cancer with PVC manufacturers; and lung, bone, and bone marrow cancer with radiologists and uranium miners.

Environment

Radiation is believed to cause 1–2% of all cancer deaths. Ultraviolet radiation from the sun accounts for a majority of melanoma deaths. Other sources of radiation are x rays, radon gas, and ionizing radiation from nuclear material.

Several studies have shown a link between asbestos and cancer. Chlorination of water may account for a small rise in cancer risk. However, the main danger from environmental pollution occurs when dangerous chemicals from industries escape into the surrounding environment. It has been estimated that 1% of cancer deaths are due to air, land, and water pollution.

Symptoms

Cancer is a progressive disease and goes through several stages. Each stage may produce a number of symptoms. Some symptoms are produced early and may occur due to a tumor that is growing within an organ or a gland. As the tumor grows, it may press on the nearby nerves, organs, and blood vessels. This growth causes pain and some pressure, which may be the earliest warning signs of cancer.

Despite the fact that there are over 100 different types of cancers, producing very different symptoms, the American Cancer Society (ACS) has established the following seven symptoms as possible warning signals of cancer:

- changes in the size, color, or shape of a wart or a mole
- a sore that does not heal
- persistent cough, hoarseness, or sore throat
- a lump or thickening in the breast or elsewhere
- unusual bleeding or discharge
- chronic indigestion or difficulty in swallowing
- any change in bowel or bladder habits

Many other diseases besides cancer can produce the same symptoms. However, it is important to have these symptoms checked, as soon as possible, especially if they linger. The earlier a cancer is diagnosed and treated, the better the chance of cure. Many cancers such as breast cancer may not have any early symptoms. Therefore, it is important to undergo routine screening tests such as breast self-exams and mammograms.

Malignant—A general term for cells and the tumors they form that can invade and destroy other tissues and organs.

Metastasis (plural, metastases)—The spread of cancer from one part of the body to another.

Neoadjuvant therapy—The administration of chemotherapy, hormone therapy, or radiation therapy before surgery. It is usually done to shrink the volume of the tumor.

Pap (Papanicolaou) test—Pap smear; removal of cervical cells to screen for cancer. The test was invented by and named for a Greek physician, George Papanicolaou, who was an early pioneer in cancer detection.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Sore—An open wound, bruise, or lesion on the skin.

Targeted therapy—In cancer treatment, a type of drug therapy that blocks tumors by interfering with specific molecules that the cancer cells need for growth. Also called biologic therapy, targeted therapy is less harmful to normal cells than traditional chemotherapy.

Tumor—An abnormal growth resulting from a cell that lost its normal growth control restraints and started multiplying uncontrollably.

X rays—High-energy radiation used in high doses, either to diagnose or treat disease.

Diagnosis

Examination

Diagnosis of many cancers begins with a thorough physical examination and a complete medical history. The doctor will observe, feel, and palpate (apply pressure by touch) different parts of the body in order to identify any variations from the normal size, feel, and texture of the organ or tissue.

As part of the physical exam, the doctor will inspect the patient's mouth. By focusing a light into the mouth, the physician will look for abnormalities in color, moisture, surface texture, or presence of any thickening or sore in the lips, tongue, gums, the hard palate on the roof of the mouth, and the throat. To detect thyroid cancer, the doctor will observe the front of the neck for swelling. He or she may gently manipulate the neck and palpate the front and side surfaces of the thyroid gland (located at the base of the neck) to detect any nodules or tenderness. As part of the physical examination, the doctor will also palpate the lymph nodes in the neck, under the arms, and in the groin. Many illnesses and cancers cause a swelling of the lymph nodes.

The doctor may conduct a thorough examination of the skin to look for sores that have been present for more than three weeks and that bleed, ooze, or crust; irritated patches that may itch or hurt; and any change in the size of a wart or a mole.

Examination of the female pelvis is used to detect cancers of the ovaries, uterus, cervix, and vagina. In the visual examination, the doctor looks for abnormal discharges or the presence of sores. Then, using gloved hands the physician palpates such internal pelvic organs as the uterus and ovaries to detect any abnormal mass. Breast examination includes visual observation, in which the doctor looks for any discharge, unevenness, discoloration, or scaling. The doctor palpates both breasts to feel for masses or lumps.

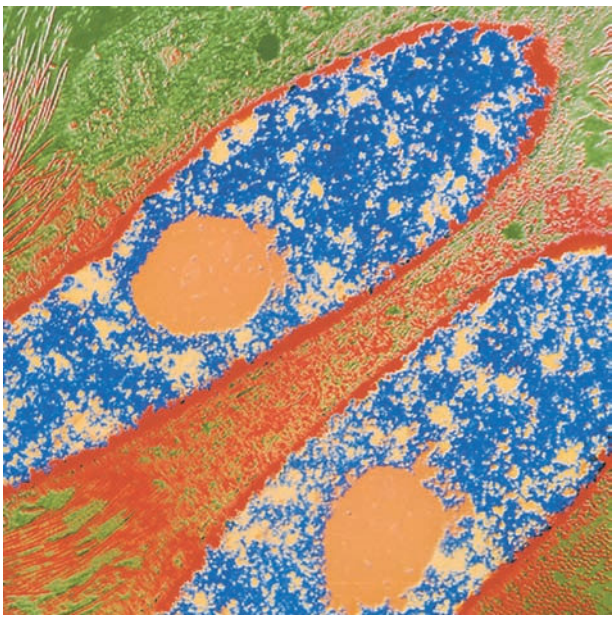
For males, inspection of the testicles, rectum, and the prostate is also included in the physical examination. The doctor inserts a gloved finger into the rectum and rotates it slowly to feel for any growths, tumors, or other abnormalities. The doctor also conducts an examination of the testes, in which the doctor observes the genital area and looks for swelling or other abnormalities. The testicles are palpated to identify any lumps, thickening, or differences in the size, weight, and firmness.

Tests

The doctor may order diagnostic tests if an abnormality has been detected on physical examination, or if the patient has some symptom that could be indicative of cancer.

Laboratory studies of sputum (sputum cytology), blood, urine, and stool can detect abnormalities that may indicate cancer. Sputum cytology is a test in which the phlegm that is coughed up from the lungs is microscopically examined. It is often used to detect lung cancer. Many blood tests used for cancer detection are typically easy to perform. The blood sample is obtained

WWW.BOOKBAZ.IR



A transmission electron micrograph (TEM) of two spindle cell nuclei from a human sarcoma. Sarcomas are cancers of the connective tissue (bone, nerves, smooth muscle). *(Dr. Brian Eyden/SPL/Photo Researchers, Inc.)*

by a lab technician or a doctor by inserting a needle into a vein and is relatively painless. Blood tests can be either specific or nonspecific. Often, in certain cancers, the cancer cells release particular proteins called tumor markers, and blood tests can be used to detect the presence of these tumor markers. However, with a few exceptions, tumor markers are not used for routine screening of cancers, because several noncancerous conditions also produce positive results. Blood tests are generally more useful in monitoring the effectiveness of the treatment, or in following the course of the disease and detecting recurrent disease.

Such imaging tests as computed tomography scans (CT scans), magnetic resonance imaging (MRI), ultrasound, positron emission tomography (PET) scans, and fiberoptic scope examinations help the doctors determine the location of the tumor even if it is deep within the body. Conventional x rays are often used for initial evaluation because they are relatively cheap, painless, and easily accessible. In order to increase the information obtained from a conventional x ray, air or a dye (such as barium or iodine) may be used as a contrast medium to outline or highlight parts of the body.

The most definitive diagnostic test is the biopsy, wherein a piece of tissue is surgically removed for microscope examination. Besides confirming a cancer, the biopsy also provides information about the type of cancer, the stage it has reached, the aggressiveness of the cancer, and the extent of its spread. Because a biopsy provides the most accurate analysis, it is considered the gold standard of diagnostic tests.

Screening examinations conducted regularly by healthcare professionals can result in the detection of cancers of the breast, colon, rectum, cervix, prostate, testis, tongue, mouth, and skin at early stages, when treatment is more likely to be successful. Some of the routine screening tests recommended by the ACS are sigmoidoscopy (for colorectal cancer), mammography (for breast cancer), Pap smear (for cervical cancer), and the prostate-specific antigen (PSA) test (for prostate cancer). Self-examinations for cancers of the breast, testis, mouth, and skin can also help in detecting tumors before the symptoms become serious.

A revolution in molecular biology and cancer genetics has contributed a great deal to the development of several tests designed to assess the risk of getting cancers. These new techniques include genetic testing, in which molecular probes are used to identify mutations in certain genes that have been linked to particular cancers. As of 2014, however, there remain some limitations to genetic testing and its utility appears ambiguous, emphasizing the need to develop better strategies for early detection.

Treatment

Treatment and prevention of cancers continues to be the focus of a great deal of research as of 2014. Research into new cancer therapies includes cancer-targeting gene therapy, new chemotherapy agents, improved imaging modalities, cancer vaccines, and such other targeted therapies as monoclonal antibodies. Most new therapies take years of clinical testing and research.

The aim of cancer treatment is to remove all or as much of the tumor as possible and to prevent the recurrence or spread of the primary tumor. While devising a treatment plan for cancer, the likelihood of curing the cancer has to be weighed against the side effects of the treatment. If the cancer is very aggressive and a cure is not possible, then the treatment should be aimed at relieving the symptoms and controlling the cancer for as long as possible.

Cancer treatment can take many different forms, and is typically tailored to the individual patient. The decision as to which type of treatment is the most appropriate depends on the type and location of cancer, the extent to which it has already spread, the patient's age, sex, general health status, and personal treatment preferences. The major types of treatment are: surgery, radiation, chemotherapy, biological therapy, targeted therapy, hormone therapy, and bone marrow and stem cell transplantation.

Surgery

Surgery is the removal of a visible tumor and is the most frequently used cancer treatment. It is most effective when a cancer is small and/or confined to one area of the body.

Surgery can be used for many purposes:

- Treatment. Treatment of cancer by surgery involves removal of the tumor to cure the disease. This is typically done when the cancer is localized to a discrete area. Along with the cancer, some part of the normal surrounding tissue is also removed to ensure that no cancer cells remain in the area. Because cancer usually spreads via the lymphatic system, adjoining lymph nodes may be examined and sometimes are removed as well.
- Preventive surgery. Preventive or prophylactic surgery involves removal of an abnormal-looking area that is likely to become malignant over time. For example, 40% of people with a colon disease known as ulcerative colitis ultimately die of colon cancer. Rather than live with the fear of developing colon cancer, these people may choose to have the colon removed, which reduces the risk of developing colon cancer significantly.
- Diagnostic purposes. The most definitive tool for diagnosing cancer is a biopsy. Sometimes, a biopsy can be performed by inserting a needle through the skin. This procedure is called fine-needle aspiration biopsy (FNAB). At other times, the only way to obtain a tissue sample for biopsy is by performing a surgical operation.
- Palliative surgery is aimed at minimizing symptoms associated with cancer. In such cases, the tumor is usually so large or has spread so much that removing the entire tumor is not an option. For example, a tumor in the abdomen may be so large that it may press on and block a portion of the intestine, interfering with digestion and causing pain and vomiting.
- Cytoreductive surgery, also called debulking surgery, is a procedure in which the doctor removes as much of the cancer as possible and then treats the remaining area with radiation therapy or chemotherapy or both. Debulking surgery can also be used in palliative treatment to remove a part of the blockage and to relieve associated symptoms. In tumors that are dependent on hormones, removal of the organs that secrete the hormones is an option. For example, in prostate cancer, the release of testosterone by the testicles stimulates the growth of cancerous cells. Hence, a man may undergo an orchiectomy (removal of testicles) to slow the progress of the disease. Similarly, in a type of aggressive breast cancer, removal of the ovaries (oophorectomy) stops the synthesis of hormones from the ovaries and may slow the progression of the cancer.

Radiation therapy

Radiation kills tumor cells. Radiation is used alone in cases in which a tumor is unsuitable for surgery. More often, it is used in conjunction with surgery and chemotherapy. Radiation can be either external or internal. In the external form, the radiation is aimed at the tumor from outside the body. In internal radiation (also known as brachytherapy), a radioactive substance in the form of pellets, rods, or liquid is placed at the cancerous site by means of a pill, injection, or insertion in a sealed container.

Chemotherapy

Chemotherapy is the use of drugs to kill cancer cells. It destroys the hard-to-detect cancer cells that have spread and are circulating in the body. Chemotherapeutic drugs can be given in many forms. The most common administration methods include oral (by mouth) or intravenous administration. Chemotherapy may be given alone or in conjunction with surgery, radiation, or both.

When chemotherapy is used before surgery or radiation, it is known as primary chemotherapy or neoadjuvant chemotherapy. An advantage of neoadjuvant chemotherapy is that because the cancer cells have not been exposed to anti-cancer drugs, they are especially vulnerable. It can therefore be used effectively to reduce the size of the tumor for surgery or target it for radiation. The more common use of chemotherapy is adjuvant therapy, which is given to enhance the effectiveness of other treatments. For example, after surgery, adjuvant chemotherapy is given to destroy any cancerous cells that still remain in the body.

Biological and targeted therapies

Biological and targeted therapies use the body's own immune system to destroy cancer cells. Targeted therapy is a newer form of pharmacotherapy that treats cancers with drugs that target the changes in genes or proteins that cause cancer cells to grow and spread. As of 2014, targeted therapy is most often used to treat advanced or metastatic cancers. Many newer agents are used to treat a variety of cancers. The various agents being tested in clinical trials and used as treatment modalities include substances produced by the body (such as the interferons, interleukins, and growth factors); monoclonal antibodies;

WWW.BOOKBAZ.IR

small molecules; and vaccines. Unlike traditional vaccines, cancer vaccines do not prevent cancer. Instead, they are designed to treat people who already have the disease. Cancer vaccines work by boosting the body's immune system and training the immune cells to specifically destroy cancer cells. Monoclonal antibody therapy works in a similar fashion; the monoclonal antibodies bind to specific cells or cell proteins and stimulate the patient's immune system to attack those cells.

Hormone therapy

Hormone therapy is standard treatment for some types of cancers that are hormone-dependent and grow faster in the presence of particular hormones. These include cancer of the prostate, breast, and uterus. Hormone therapy involves blocking the production or action of these hormones. As a result, the growth of the tumor slows, and the patient's survival may be extended.

Bone marrow, stem cell, and cord blood transplantation

The bone marrow is the tissue within the bone cavities that contains blood-forming cells. Healthy bone marrow tissue constantly replenishes the blood supply and is essential to life.

A bone marrow transplant is the removal of marrow from one person and the transplant of the blood-forming cells either to the same person or to someone else. Bone marrow transplantation, while not a therapy in itself, is often used to "rescue" patients, by allowing those with cancer to undergo aggressive therapy. Stem cell transplants have been performed to replace bone marrow that has been destroyed by cancer, chemotherapy, or radiation therapy. Stem cells are specialized cells in the bone marrow from which the body receives a constant source of blood cells. Stem cells may also be harvested from umbilical cords, a process that is referred to as a cord blood transplant. Some cancers in which stem cell transplants may be used include leukemia, lymphoma, and multiple myeloma.

Alternatives

There are a multitude of alternative treatments available to help the person with cancer. They can be used in conjunction with, or separate from, surgery, chemotherapy, and radiation therapy. Alternative treatment of cancer is a complicated arena and a trained health practitioner should be consulted.

Although the effectiveness of such complementary therapies as acupuncture in alleviating cancer pain has not been clinically proven, many cancer patients find it safe and beneficial. Such bodywork therapies as massage and reflexology ease muscle tension and may alleviate such side effects of cancer treatment as nausea and vomiting. Homeopathy and herbal remedies used in Chinese traditional herbal medicine also have been shown to alleviate some of the side effects of radiation and chemotherapy and are recommended by many doctors.

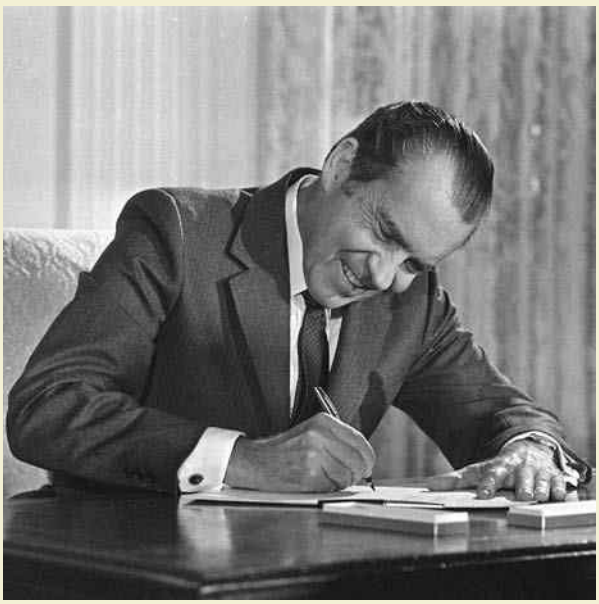
Certain foods, including many vegetables, fruits, and grains, are believed to offer protection against various cancers. However, isolation of the individual constituent of vegetables and fruits that are anticancer agents has proven difficult. In laboratory studies, vitamins such as A, C, and E, as well as compounds such as isothiocyanates and dithiolthiones found in broccoli, cauliflower, and cabbage, and beta-carotene found in carrots have been shown to protect against cancer. Studies have shown that eating a diet rich in fiber as found in fruits and vegetables reduces the risk of colon cancer. Exercise and a low-fat diet help control weight and reduce the risk of endometrial, breast, and colon cancer.

Cancer treatment team

Many different specialists generally work together as a team to treat cancer patients. An oncologist is a physician who specializes in cancer care. The oncologist provides chemotherapy, hormone therapy, and any other nonsurgical treatment that does not involve radiation. The oncologist often serves as the primary physician and coordinates the patient's treatment plan.

The radiation oncologist specializes in using radiation to treat cancer, whereas the surgical oncologist performs the operations needed to diagnose or treat cancer. Gynecologic oncologists and pediatric oncologists, as their titles suggest, are physicians involved with treating women's and children's cancers, respectively. Many other specialists also may be involved in the care of a cancer patient. For example, radiologists specialize in the use of x rays, ultrasounds, CT scans, MRI imaging, PET scans, and other techniques that are used to diagnose cancer. Hematologists specialize in disorders of the blood and are consulted in case of blood cancers and bone marrow cancers. Dermatologists are consulted for cancers of the skin, and dentists and oral surgeons are typically involved in the care of patients with cancers of the oral cavity. The samples that are removed for biopsy are sent to a laboratory, where

NATIONAL CANCER ACT OF 1971



President Richard Nixon signs the National Cancer Act at the White House, Dec 23, 1971. *(AP World Wide)*

The first decades of the twentieth century in the United States were a time of sharply decreasing mortality from many causes and a substantial increase in life expectancy. Improved hygiene, widespread vaccination, use of antibiotics, and improved scientific knowledge helped defeat some of the most common causes of death. However, while many medical fights were being won, cancer remained unconquered. As deaths from other diseases declined, cancer deaths continued to grow. By the early 1970s, cancer was the second leading cause of death in the United States.

Before the National Cancer Act, there was some governmental support for cancer research. An act of Congress had established the National Cancer Institute in 1937 with a mission of supporting cancer research and training. While some progress had been made in understanding and treating the disease, the breakthroughs remained elusive. Senator Ralph Yarborough (1903–1996) of Texas, made it his mission to improve cancer research and treatment in the United States. He formed a group of experts, including doctors, researchers, business people, and advocates, to create a plan to provide more support for the scientists working on the problem and to help encourage more scientists to get involved in cancer research.

The group led by Senator Yarborough became widely known as the Yarborough Commission. Its members produced a report that became the foundation for legislation introduced in Congress explicitly making cancer research and funding a priority of the U.S. government. On December 23, 1971, President Richard Nixon (1913–1994) signed the National Cancer Act to great fanfare. The act vastly increased funding for cancer research. In addition to providing increased funding for the National Cancer Institute, it created fifteen cancer research centers across the nation. The act also directed that the budget for the National Cancer Institute go directly to the president, bypassing the usual budgetary process and helping to ensure that funding for cancer research and treatment would not be bogged down in unrelated political issues.

The act created the National Cancer Advisory Board, as well as the President's Cancer Panel. The director of the National Cancer Institute was given broad powers in deciding how to support research by awarding grants, appointing committees, creating new training centers, and creating an international database on cancer research.

When the act was signed, many praised the president as having declared a war on cancer, and they hoped that cancer could be wiped out within a few years. Although these hopes did not come to fruition, the act made possible the governmental funding for cancer research and treatment. Between the 1970s and the early 2000s, the five-year survival rate for individuals with cancer increased more than one-third. Deaths from cancer decreased more than 18% between 1991 and 2012.

a pathologist examines them to determine the type of cancer and extent of the disease. There are many other specialties, and virtually any type of medical or surgical specialist may become involved with care of the cancer patient should it become necessary.

Prognosis

"Lifetime risk" is the phrase that cancer researchers use to refer to the probability that an individual over the course of a lifetime will develop cancer or die from it. In the United States, men have slightly less than a one in two lifetime risk of developing cancer, and for women the risk is slightly more than one in three. Overall, African Americans are more likely to develop cancer than Caucasians. Compared to Caucasians, African American men are 27% more likely to die of cancer, and the death rate among African American women is 11% higher. Hispanics, on the other hand, have the lowest rates of lung cancer incidence and mortality of any racial or ethnic group in the United States, but the highest rates of cancers associated with infections (liver, stomach, and uterine

WWW.BOOKBAZ.IR

cervix). Asian Americans and Pacific Islanders have the lowest overall rates of cancer incidence and mortality among ethnic groups in the United States. Native Americans and Alaska Natives have unusually high rates of kidney cancer, thought to result from their high rates of smoking and obesity.

Many cancers are curable if detected and treated in their early stages. A cancer patient's prognosis is affected by many factors, particularly the type of cancer the patient has, the stage of the cancer, the extent to which it has metastasized, and the aggressiveness of the cancer. In addition, the patient's age, general health status, and the effectiveness of the treatment being pursued are important factors.

To help predict the future course and outcome of the disease and the likelihood of recovery from the disease, doctors often use statistics. The 5-year survival rates are the most common measures used. The number refers to the proportion of people with cancer who are expected to be alive five years after initial diagnosis compared with a similar population that is free of cancer. It is important to note that while statistics can give some information about the average survival experience of cancer patients in a given population, they cannot be used to indicate individual prognosis because no two patients are exactly alike.

Prevention

According to nutritionists and epidemiologists from leading universities in the United States, a person can reduce the chances of getting cancer by following some simple guidelines:

- eating plenty of vegetables and fruits
- exercising vigorously for at least 30 minutes on 5 or more days every week. Forty-five to sixty minutes of moderate to vigorous physical activity is preferable.
- avoiding excessive weight gain
- avoiding tobacco products (even secondhand smoke)
- decreasing or avoiding consumption of animal fats and red meats
- avoiding excessive amounts of alcohol
- avoiding the midday sun (between 10 A.M. and 4 P.M.), when the sun's rays are the strongest
- avoiding risky sexual practices and limiting the number of sexual partners
- avoiding known carcinogens in the environment or work place

Cancer chemotherapy drugs *see* **Anticancer drugs**

Cancer markers

Definition

Cancer markers—also called cancer biomarkers or tumor markers—are substances—usually proteins—in tissue, blood, urine, or other body fluids that may be associated with certain cancers. As of 2014, there were more than 20 markers in clinical use, and they were a major focus of cancer research.

Purpose

Cancer markers are rarely specific enough to diagnose cancer; however, they are used to:

- screen people at high risk for certain cancers
- confirm a diagnosis in conjunction with other clinical findings
- stage cancers or help determine the extent of a cancer—higher cancer-marker levels may indicate more advanced cancer and/or a worse prognosis
- help determine where a metastasized cancer originated, which is important for identifying the type of cancer and guiding treatment
- plan primary and adjuvant treatments, including choosing chemotherapy and targeted drugs
- predict responses to treatment and prognosis
- monitor response to treatment
- monitor progression of advanced cancer
- monitor for cancer recurrences

The most common use of cancer markers is to monitor the effects of treatment. Markers in blood or urine can be easily followed to gage the effects of treatment and for many years after treatment to detect recurrences. Cancer-marker testing is far less invasive and expensive than imaging techniques for monitoring cancer. Decreases in cancer-marker levels suggest that the cancer is responding to treatment. Stable or increasing levels suggest that the cancer is not responding and that a different treatment may be necessary—the exception is a temporary increase in a cancer marker during treatment, as markers are released into the bloodstream by dying cells. Periodic cancer-marker testing can sometimes detect a recurrence months earlier than other diagnostic methods. Cancer markers on cells that are detectable in tumor tissue from a biopsy or surgery—but not in body fluids—are usually measured only once, to confirm diagnosis and help select treatments.

Description

Cancer markers are either produced by cancer cells (tumor-derived) or by the body in response to cancer (tumor-associated). Although most cancer markers are also produced by normal cells, cancer cells may produce them in much greater amounts and leak them into the blood, urine, or stool as the cancer cells grow and multiply (proliferate). The usefulness of cancer markers depends on their specificity and sensitivity. Some markers are associated with many types of cancer as well as with non-cancerous (benign) conditions; other markers are associated with just one or a few cancers. Although some markers are always found at high levels in certain cancers; the levels of most cancer markers are much less predictable.

Most cancer markers are proteins. They may be antigens on the surfaces of or secreted by cancer cells, hormones, receptors for hormones or growth-stimulating factors, enzymes, or antibodies (immunoglobulins). Some cancer markers—such as alpha-fetoprotein (AFP), carcinoembryonic antigen (CEA), and cancer antigen (CA) 72-4—are proteins that are normally produced during fetal development and decrease soon after birth. Such markers are produced by many types of cancer cells that have dedifferentiated—reverted to immature cell types—and, therefore, are very nonspecific. However, they are useful for monitoring cancer progression and response to treatment.

Cancer markers are most often measured in laboratories by immunological tests. A blood or tissue sample is reacted with antibodies specific for the marker. The amount of antibody bound to markers in the sample is measured. Results are usually available within a few days. Some cancer markers are measured by polymerase chain reaction (PCR) to quantify their DNA. Cancer-marker tests are approved by the U.S. Food and Drug Administration (FDA), and guidelines for their use are established by organizations such as the American Society of Clinical Oncology (ASCO). Not all cancer-marker tests are widely available.

Newer types of cancer markers being studied as of 2014 include:

- protein profiles or "signatures"—multiple proteins that are all increased in specific cancers
- autoantibodies—antibodies that the immune system produces against the body's own proteins because of the excess produced by tumor cells
- gene changes (mutations) in cancer cells
- epigenetic changes—changes to genetic material that do not change gene sequences
- specific RNAs (genetic material) that can be detected in the blood

WWW.BOOKBAZ.IR

Prostate-specific antigen (PSA)

PSA—a blood screen for prostate cancer—is the most widely used cancer marker. It is the only marker used to screen a general population—men over age 50 and high-risk men over 40. PSA is tissue-specific—it is produced only by the prostate gland and may be overproduced by prostate cancers. Once **prostate cancer** is diagnosed, PSA levels can help determine the cancer stage and are very useful for monitoring response to treatment and recurrence. Any PSA detected following prostate removal (**prostatectomy**) indicates the tissue was not all removed or the cancer has metastasized (spread to other parts of the body). However, although prostate cancer usually causes high PSA levels, men with healthy prostates can have high levels, and normal levels do not mean the absence of cancer. Furthermore, PSA is increased in other common non-cancerous conditions. Two large trials indicated that PSA screening leads to only a small reduction in prostate cancer deaths, and it is unclear whether the benefits of PSA screening outweigh the harm of follow-up tests and treatment for cancers that would never become life-threatening. PSA can be detected in blood serum in two states—bound and free. Measuring both states can increase specificity and reduce unnecessary biopsies.

Several new prostate cancer marker tests were introduced in 2013.

- The Prostate Health Index (PHI) is a screening test that measures three forms of PSA in the blood.
- The 4Kscore is a screening test that measures PSA and another cancer marker in the blood.
- Prostarix is a urine screening test that measures markers that leak from the prostate into urine.
- Three new tests measure the activity of genes linked to prostate cancer to help decide whether a second biopsy is necessary if the first did not find cancer: Progensa PCA3 measures gene activity in the urine, and Prostate Core Mitomic and ConfirmMDx measure gene activity in biopsy tissue.
- Three other new tests—Prolaris, Genomic Prostate Score (Oncotype Dx), and ProstaVysion—measure gene activities in prostate biopsy tissue that are associated with more aggressive cancers to help determine whether a diagnosed cancer is likely to grow and spread. This can help men with low-risk cancers decide whether to choose "watchful waiting" or aggressive treatment.

Prostatic acid phosphatase (PAP) was once thought to be a blood marker for prostate cancer, but was replaced by PSA. However, PAP may help diagnose **multiple myeloma** and lung cancer.

AFP and human chorionic gonadotropin (hCG)

AFP, which is normally produced by fetal tissue, is the most widely used marker for primary **liver cancer** and germ-cell tumors including some testicular cancers and rare types of **ovarian cancer**. Blood AFP levels are high in 70% of liver cancers and are used for screening in China, where liver cancer rates are high. AFP is also used to stage liver and germ-cell cancers, monitor treatment responses, and screen for cancer recurrences.

hCG, which is normally produced by the placenta during **pregnancy**, consists of two protein subunits, alpha and beta. The beta subunit is increased in serum and urine during early pregnancy and with some germ-cell tumors. Tumors that secrete beta-hCG are typically ovarian and testicular tumors with embryonic tissue, as well as gestational trophoblastic tumors, such as **choriocarcinoma**. Such tumors may also secrete AFP, and hCG and AFP tests are often used in combination. Very high AFP or beta-hCG levels from **testicular cancer** indicate aggressive disease and poor prognosis.

CEA

High blood plasma levels of CEA are most often associated with colorectal cancer. CEA levels are used to monitor patients with colorectal cancer, evaluate the success of surgery, diagnose metastases, and help with prognosis and early detection of recurrence. CEA levels are also used in **breast cancer** to assess response to treatment and diagnose recurrence. However, CEA is very nonspecific and can be increased with many types of cancer as well as in some benign conditions. CEA levels also may be elevated in the elderly and in smokers.

Cancer antigens

CA 15-3/CA 27.29 are different blood tests for the same antigen and are used to assess response to breast cancer treatment and monitor for recurrence. CA 27.29 is elevated in 80% of breast cancers, although neither test can detect early cancer. Both tests also may be positive with other cancers and non-cancerous conditions.

CA 125 is the standard blood marker followed during and after treatment for the most common type of ovarian cancer, as well as for fallopian tube and primary peritoneal cancers. Although CA 125 is produced by a number of cell types, 80% of women with ovarian cancer and more than 90% with advanced cancer have elevated levels. However, CA 125 levels may also increase during menstruation and pregnancy

and with various other cancers and benign conditions. Since ovarian cancer is somewhat rare, high CA 125 is more likely due to some other condition.

CA 19-9 was developed as a colorectal cancer blood marker but is more often used for pancreatic cancer, where higher levels are associated with more advanced disease. It is used to monitor the course of pancreatic cancer and response to treatment, as well as to determine the aggressiveness of **bladder cancer**. CA 19-9 is related to the Lewis blood group, and only patients positive for the Lewis blood group antigen will test positive for CA 19-9. Higher CA 19-9 is also associated with other digestive tract and abdominal cancers and with some benign conditions.

CA 72-4 is slightly elevated with most carcinomas, but is primarily associated with **stomach cancer**.

Receptors and hormones

Human epidermal growth factor receptor 2 (HER2) is a cancer marker measured in biopsy tissue. HER2-positive breast cancers, as well as stomach and esophageal cancers, can be treated with the targeted drug trastuzumab (Herceptin). Cancer cells with normal amounts of HER2 will not respond to trastuzumab. About 20% of breast cancers are HER2-positive. HER2-positive cancers usually grow and spread faster than other types of cancer.

All breast tumor biopsy samples are tested for estrogen receptors (ER) and progesterone receptors (PR) as well as for HER2. Most breast cancers in postmenopausal women are ER-positive and grow in response to estrogen. About two-thirds of breast cancers are positive for at least one of these hormone receptors. ER- and PR-positive breast cancers can be treated with hormonal therapies, tend to grow more slowly, and have a better prognosis than other breast cancers. Some gynecologic cancers are also tested for hormone receptors.

Epidermal growth factor receptor (EGFR or HER1) may be increased in some cancer tissues and is a sign of a fast-growing, spreading, and hard-to-treat cancer that may be aggressively treated with drugs that block EGFR. Some lung cancers—especially those in women, Asians, and nonsmokers—have EGFR gene mutations that make it more likely that certain drugs will be effective.

Endocrine-gland tumors over-secrete their corresponding hormones, and serial measurements can be used to monitor treatment.

- Medullary thyroid carcinoma (MTC) can secrete calcitonin, which normally regulates calcium levels. Calcitonin is one of the few markers that can help detect early cancer and can be used to screen for MTC, which, although rare, is often inherited.
- Pituitary gland tumors may secrete growth hormone or cortisol.
- Carcinoid tumors secrete serotonin.
- Some pancreatic tumors secrete insulin.
- Breast cancer cells may secrete prolactin and estrogen.
- Pheochromocytomas secrete catecholamines.
- Blood levels of inhibin can be high with a rare type of ovarian cancer.

Enzymes

Neuron-specific enolase (NSE) is found mainly in neurons and neuroendocrine cells and is elevated in tumors derived from these tissues, including **neuroblastoma** and **small cell lung cancer**. NSE blood levels can provide information about the extent of disease, prognosis, and response to treatment.

Several serum enzymes can help detect cancer metastases. Tumors that metastasize to the liver increase serum levels of alkaline phosphatase, gamma-glutamyltransferase, and transaminases. Tumors that metastasize to bone sometimes secrete elevated alkaline phosphatase.

Lactate dehydrogenase (LDH) is an enzyme found throughout the body, and high levels occur with many conditions. However, LDH blood levels can be used to assess the stage, prognosis, and response to treatment of testicular and other germ-cell cancers, as well as Ewing sarcoma, non-Hodgkin lymphoma, and some types of leukemia.

Other proteins

Bence-Jones protein was the first identified cancer marker. It appears in the urine of patients with multiple myeloma and Waldenstrom macroglobulinemia. It is the light-chain portion of an immunoglobulin (Ig) known as monoclonal Ig or M protein. M or Bence-Jones proteins (also called free light chains), as well as the amounts of each Ig class, can be measured in the blood to assist in diagnose and guide treatment.

- Beta-2 microglobulin (B2M) is a small membrane protein measured in blood, urine, or cerebrospinal fluid for prognosis and monitoring treatment responses in multiple myeloma, chronic lymphocytic leukemia, and some lymphomas. B2M levels are higher in patients with poorer prognosis.
- Chromogranin A can be secreted into the blood by some neuroendocrine tumors such as small cell lung

WWW.BOOKBAZ.IR

cancer, neuroblastoma, and carcinoid tumors. High levels are detected in about one-third of patients with localized cancers and about two-thirds of those with advanced cancers.

- Fibrin or fibrinogen can be measured in urine to monitor progression of bladder cancer and response to treatment.
- Nuclear matrix protein 22 in the urine is used to monitor treatment response in bladder cancer.
- Thyroglobulin in the blood is used to monitor treatment response and recurrence of thyroid cancers. Antibodies against thyroglobulin are often measured as well.
- Urokinase plasminogen activator and plasminogen activator inhibitor are used to determine breast cancer tumor aggressiveness and guide treatment.
- Some ovarian cancers have multiple HE4 genes and make more HE4 protein that can be measured in blood and used to guide treatment, most often in patients with normal CA 125 levels.
- Squamous cell carcinoma (SCC) antigen was first identified in cervical cancers and is a marker for SCCs of the cervix, head and neck, lung, and skin.
- The amount of CD20 on blood cells is used to determine whether targeted therapy is appropriate for non-Hodgkin lymphoma.
- Cytokeratin fragment 21-1 in the blood can help detect lung cancer recurrence.
- S-100 is present in most melanoma cells. Biopsy samples may be tested to help with diagnosis, and blood levels are sometimes used to diagnose metastasized melanoma.
- Soluble mesothelin-related peptide is sometimes used as a blood screen for people at high risk for mesothelioma or to detect recurrence.
- A five-protein signature in the blood, known as Ova1, is used to assess suspected ovarian cancer before surgery.

Genes

The BCR-ABL fusion gene is formed when the ABL gene from chromosome 9 breaks off and joins the BCR gene on chromosome 22 to form the Philadelphia chromosome. This occurs in most chronic myelogenous leukemias and some acute lymphoblastic and acute myelogenous leukemias. The fusion can be detected in the blood or bone marrow by PCR and is used to confirm diagnosis, monitor disease status, and guide treatment.

The KRAS gene is mutated in 30–40% of colorectal tumors. ASCO recommends that people with metastasized **colon cancer** be tested for KRAS mutations, since cancer with these mutations cannot be treated with drugs that target EGFR. KRAS mutation analysis is also used for **non-small cell lung cancer**, since cancers with KRAS mutations do not respond to the drugs erlotinib and gefitinib.

- Specific mutations in the BRAF gene produce a protein that can increase the growth and spread of cancer cells, especially melanomas and colorectal cancers, and can be targeted with specific drugs. Colorectal cancers with BRAF mutations cannot be treated with drugs that target EGFR.
- Mutation analysis of EGFR on tumor cell surfaces can help determine treatment and prognosis for non-small cell lung cancer.
- Rearrangements in the ALK gene that codes for anaplastic lymphoma kinase can be detected in tumor tissue and are used to help determine treatment and prognosis of non-small cell lung cancer and anaplastic large cell lymphoma.
- A 21-gene signature known as Oncotype DX and a 70-gene signature called the Mammaprint are used to analyze breast cancer tumors for risk of recurrence.
- Chromosomes 3, 7, 17, and 9p21 in the urine can be used to help monitor recurrence of bladder cancer.

Risks

Cancer markers are most useful for selecting targeted drug therapies, monitoring the effects of treatment, and detecting recurrences. They are rarely useful for detecting early cancers. Furthermore, false positives can lead to emotional distress and unnecessary tests; false negatives can result in foregoing additional testing or treatment that might be beneficial. Cancer marker usefulness has been limited because:

- Most people have small amounts of cancer markers in their blood.
- Blood markers tend to be high only with advanced cancers.
- Some people with cancer never have high cancer-marker levels.
- Many other conditions can cause high cancer-marker levels.

Only cancer markers that were elevated before treatment should be used for monitoring during or after treatment. Timing of the tests is very important: each marker has a unique time-span in the blood, and to monitor treatment effectiveness, enough time must have passed for the marker to be cleared from the blood. Normal and high ranges for many cancer markers vary significantly between testing labs. If

KEY TERMS

Alpha-fetoprotein; AFP—A fetal blood protein that is secreted by some cancers.

Antibodies—Immune-system proteins that recognize specific antigens, such as proteins on tumor cells.

Antigen—A protein or other molecule that evokes a specific immune response.

Beta-2 microglobulin; B2M—A small membrane protein that may be elevated in some cancers.

Biopsy—The removal of a small piece of tissue for examination and testing.

Cancer antigen; CA—Marker proteins for some types of cancer.

Carcinoembryonic antigen; CEA—A fetal protein that is present at high levels in the blood with some types of cancer, such as breast or digestive-system cancers.

Epidermal growth factor receptor; EGFR—EGFR1 (HER1); a cell-surface protein that initiates growth and proliferation and is a marker for certain cancers.

Estrogen receptor; ER—A cell-surface protein that binds the female hormone estrogen; present on ER-positive breast cancer cells.

HER2—Human epidermal growth factor receptor 2 (EGFR2); also called HER2/neu or erbB-2; overproduced in HER2-positive breast cancers.

Human chorionic gonadotropin; hCG—A hormone secreted by the placenta in early pregnancy and produced by some tumors; beta-hCG is a marker for some germ-cell cancers.

Immunoglobulins; Igs—Antibodies; some types of immunoglobulins or portions of immunoglobulins called light chains, including the Bence-Jones protein, can be used as markers for some types of cancer.

Lactate dehydrogenase; LDH—An enzyme that can be a marker in the blood for some cancers.

Neuron-specific enolase; NSE—An enzyme that may be elevated in tumors originating in neuroendocrine cells.

Polymerase chain reaction; PCR—A method for directly detecting and quantifying specific DNA or RNA in blood or tissue.

Progesterone receptor; PR—A protein on the surface of cells that binds the female hormone progesterone; a marker on PR-positive breast cancer cells.

Prostate specific antigen; PSA—A marker used as a preliminary screen for prostate cancer.

Prostatic acid phosphatase; PAP—A potential cancer marker for multiple myeloma and lung cancer.

Receptor—A molecule, usually a protein, inside or on the surface of a cell that binds a specific chemical group or molecule, such as a hormone or growth factor, to initiate a sequence of events.

Targeted drug—A drug that interferes with specific molecules involved in cancer cell growth and/or survival; often chosen on the basis of a cancer marker.

possible, serial testing should always be performed by the same lab so that results are comparable. Results must also use the same units of measurement. Commercial labs have tests for many more cancer markers; however, some advertised tests have not been proven effective, and others have been taken off the market at the request of the FDA.

ORGANIZATIONS

American Cancer Society, 250 Williams Street NW, Atlanta, GA, USA, 30303, (800) 227-2345, http://www.cancer.org.

The ACS is a nationwide, community-based, volunteer health organization dedicated to eliminating cancer as a major health problem. The ACS has more than 900 local offices and maintains an excellent website that includes information on cancer markers.

American Society of Clinical Oncology, 2318 Mill Road, Suite 800, Alexandria, VA, USA, 22314, 1(571) 483-1300, Fax: 1(571) 366-9537, (888) 651-3038, contactus@cancer.net, http://www.asco.org.

ASCO is a professional organization of some 30,000 oncologists. It publishes journals and sponsors the Conquer Cancer Foundation and the informative Cancer.Net and Cancer Portals websites. It develops guidelines for the use of cancer markers.

National Cancer Institute, 6116 Executive Boulevard, Suite 300, Bethesda, MD, USA, 20892-8322, (800) 4-CAN-CER (422-6237), http://www.cancer.gov.

The NCI is the institute within the U.S. National Institutes of Health that is concerned with research and education on prevention, diagnoses, treatments, and cures for cancer. Its Early Detection Research Network focuses on research and development of biomarkers and technologies for the clinical application of early cancer detection strategies. The NCI maintains a comprehensive website that includes information on cancer markers.

U.S. Food and Drug Administration, 10903 New Hampshire Avenue, Silver Spring, MD, USA, 20993-0002, (888) INFO-FDA (463-6332), http://www.fda.gov.
The FDA is responsible for approving new drugs and tests for cancer markers, as well as for assuring the safety, effectiveness, and security of human and veterinary drugs, biological products, medical devices, and vaccines.

Margaret Alic, PhD

Cancer screening guidelines

Definition

Cancer screening guidelines are examinations, tests, and/or procedures that that are suggested for some or all adults of a certain age to detect common cancers at early stages when they may be most treatable.

Purpose

Colorectal cancer (CRC)—cancer of the colon or rectum—is the third most common cancer, other than **skin cancer**, in the United States and the third leading cause of cancer-related deaths. An estimated 65,000 women and 71,830 men were diagnosed with CRC in the United States in 2014, and an estimated 24,040 women and 26,270 men died from the disease. The risk of CRC increases with age—more than 90% of diagnoses are in people over 50. African Americans and native Alaskans are at greater risk and have a lower survival rate. However, CRC is often curable if detected early. The majority of CRCs begin as abnormal tissue—lesions or polyps—on the colon wall and usually take 10–15 years to develop into cancer. Studies indicate that early screening to identify and remove these abnormal growths may help prevent about 43% of CRC deaths in women and about 29% in men. CRC deaths declined 2% during the 1990s and 3% from 2000 to 2010, primarily due to early screening and treatment. Progress in reducing CRC death rates could be accelerated by improving access to and use of screening and standard treatment for all populations.

Breast cancer is the most commonly diagnosed cancer in women worldwide and the second leading cause of cancer deaths in American women. In 2014, an estimated 232,670 women were diagnosed with invasive breast cancer that had the potential to spread to other organs, and 62,570 were diagnosed with non-invasive breast cancer. Approximately 40,000 women died of the disease in 2014. **Mammography** can detect

breast lumps one to three years before they can be felt. Death rates have declined since the 1990s due to early detection through screening and improved treatment options. It has been estimated that 16% of breast-cancer deaths could be prevented by regular mammography screening beginning at age 40.

Cervical cancer is the fourth most common cancer in women and the fourth leading cause of death. It can take several years to develop and occurs most often in women over 40. Routine screening with a **Pap test** can identify cervical cancer at early stages when it is highly curable. Pap tests have been available for 50 years and are credited with the overall decline in cervical cancer. Screening can also detect **human papillomavirus** (HPV) infection, which causes almost all cervical cancers.

Prostate cancer is the second most common cause of cancer deaths in American men. About one in six will be diagnosed with prostate cancer during their lifetime. In 2014 in the United States, an estimated 233,000 men were diagnosed with prostate cancer, with 29,480 deaths. Most cases are diagnosed in men aged 65 and older. Prostate cancer is more common in African American men and in those with a family history of the disease. Since the introduction of blood tests for prostate-specific antigen (PSA) in the 1990s, more prostate cancers are being detected early, before they spread to other organs and become more difficult to treat. However, screening for prostate cancer is controversial:

- About one-third of men with positive PSA results do not have cancer.
- The available tests do not detect all prostate cancers.
- The majority of prostate cancers are slow-growing and may never affect health or life expectancy.
- Side effects of prostate cancer treatment, including impotence and incontinence, can be more harmful than the cancer.
- PSA screening of men aged 55–69 prevents one prostate cancer death for every 1,000 men screened over a ten-year period.

Cancer screening guidelines for at least some people have also been established for skin, lung, ovarian, and endometrial (uterine lining) cancers.

Description

Colorectal cancer

SCREENING TYPES. Screening tests and procedures for precancerous polyps and lesions and/or CRC differ greatly in sensitivity, specificity, and convenience:

- Fecal occult blood testing (FOBT)—also called stool occult blood, hemoccult card testing, or guaiac smear testing (gFOBT)—detects occult (hidden) blood in the stool from damaged blood vessels on the surfaces of larger polyps or cancers. The test cannot distinguish between blood from the colon or elsewhere in the gastrointestinal tract, such as the stomach or esophagus.
- Fecal immunochemical testing (FIT)—sometimes called immunochemical or immunoassay FOBT—also detects blood in the stool. Unlike FOBT, food and drugs do not interfere with FIT, sample collection is easy, and it is more specific for blood from the colon. Like FOBT, FIT will not detect a non-bleeding cancerous tumor.
- Stool DNA testing (sDNA) detects abnormal DNA from cancer or polyps. It is more expensive than FOBT or FIT.
- Flexible sigmoidoscopy uses a flexible lighted tube with a small video camera to examine the inside of the rectum and the lower third of the colon. Visualized polyps and lesions can be removed during the procedure.
- Colonoscopy is similar to sigmoidoscopy but examines the entire length of the colon. Polyps, lesions, and cancerous tumors can be removed during the procedure.
- Double-contrast barium enemas are x rays of the rectum and colon with barium to enhance viewing.
- Computed tomographic colonography (CTC), or virtual colonoscopy, visualizes the rectum and colon by combining and analyzing multiple x-ray images. It is not reliable for detecting smaller polyps (less than 1 cm), which account for 80% of growths.

Colonoscopy is the most sensitive method for detecting and removing lesions, polyps, and cancerous tumors. It also is the most invasive, the most expensive, and requires **sedation**. **Sigmoidoscopy**, colonoscopy, barium **enemas**, and CTC all require **bowel preparation**, which many people find inconvenient and unpleasant. In contrast, stool testing is usually performed at home using a simple kit that is sent to a laboratory for developing. FOBT performed by a physician during a digital rectal exam (DRE) can indicate bleeding but is not an adequate CRC screen. Any screening that detects bleeding or polyps will require a colonoscopy.

GUIDELINES. The American College of Gastroenterology guidelines distinguish between screening tests for prevention and detection:

- Beginning at age 50, everyone should have FIT every year for cancer detection (followed by colonoscopy if

WWW.BOOKBAZ.IR

results are positive) and a screening colonoscopy every 10 years for cancer prevention.

- Flexible sigmoidoscopy can be performed every five to ten years, but should not replace colonoscopy.
- sDNA may be performed every three years.
- CTC can be performed every five years for those who decline colonoscopy and is preferred over a double-contrast barium enema as a radiographic test. It is followed by colonoscopy if polyps are detected.
- African Americans should be screened by colonoscopy every ten years beginning at age 45, and those at higher risk should be screened more frequently. African Americans tend to be diagnosed with CRC at a younger age and survive for a shorter period. They also have more right-sided polyps and cancers, which are especially dangerous.
- People at high CRC risk should have screening colonoscopy at more frequent intervals (colonoscopic surveillance). Medicare provides for surveillance colonoscopy every two years for those at high risk.

The American Cancer Society (ACS) guidelines recommend that, at the very least, everyone, beginning at age 50, should have annual screenings by gFOBT, FIT, or sDNA, although sDNA intervals are uncertain. All of these should be multiple stool take-home tests rather than a single test in a doctor's office. A colonoscopy should be performed if a test is positive. However, screening tests that find both polyps and early cancer are preferable. Everyone willing to have more invasive testing and with access to the tests should follow one of these screening schedules beginning at age 50:

- flexible sigmoidoscopy every five years
- double-contrast barium enema every five years
- CTC every five years
- colonoscopy every 10 years or immediately if one of the other three procedures is positive
- more frequent schedules for those at high risk due to personal or family history

The U.S. Preventive Services Task Force (USPSTF) screening guidelines call for:

- screening of ages 50–75 at average risk by high-sensitivity FOBT, sigmoidoscopy, or colonoscopy, not sDNA or CTC
- more frequent screening for those at higher risk
- no routine screening of adults aged 76–85
- no screening of those over age 85

HIGHER RISK. People at higher risk for CRC require more frequent and/or more sensitive screening, beginning as early as age 40. Risk factors for CRC include:

- history of colon or rectal polyps or CRC
- history of inflammatory bowel disease, Crohn's disease, or ulcerative colitis
- a family history (parent, sibling, or child) with colorectal polyps or CRC, polyposis coli syndrome (numerous colonic polyps), or hereditary CRC syndromes such as familial adenomatous polyposis (FAP) or hereditary non-polyposis colorectal cancer (HNPCC or Lynch syndrome)

A 2013 study indicated that people with first-degree relatives (parents, siblings, or children) with polyps linked to cancer (adenomas) were at 35–70% increased risk of developing CRC. Screening guidelines currently recommend colonoscopy every five years beginning at age 40 for those with first-degree relatives diagnosed with advanced adenomas or CRC before age 60. However, people with second-degree (aunts, uncles, grandparents) and third-degree (nieces, nephews, cousins, great-grandparents) relatives with adenomas were also at increased risk, and screening guidelines may therefore miss 10% of colon cancers.

Individuals with a significant family history of colorectal polyps or cancer, especially FAP or HNPCC, may have **genetic testing** for CRC-associated gene mutations. FAP confers a lifetime CRC risk of almost 100%, usually before age 40. People who test positive for a FAP-associated gene mutation should begin colonoscopy screening as teenagers. HNPCC confers a lifetime CRC risk that may be as high as 80%. Members of families known to carry HNPCC-associated gene mutations who have not been tested or who test positive for a mutation should begin colonoscopy screening in their early 20s.

Skin cancer

People at higher risk for **melanoma**, including those previously diagnosed with melanoma or with a strong family history of melanoma, should have their skin examined regularly by a physician. Otherwise, guidelines for skin-cancer screening are self-examination, followed by a physician's exam if certain skin conditions are noted, such as:

- suspicious skin areas
- non-healing sores or blemishes
- changes in a freckle or mole

Lung cancer

The National Cancer Institute (NCI) National Lung Screening Trial of more than 50,000 current

and former heavy smokers aged 55–74 reported 20% fewer lung cancer deaths among those screened with low-dose computed tomography (LDCT) compared with **chest x-ray** screening. The ACS and other guideline developers agree that people who meet all of the following criteria should be offered annual LDCT screening:

- ages 55–74
- in reasonably good health
- cigarette smoking history of at least 30 pack-years and either still smoking or quit within the last 15 years

The USPSTF recommends that patients and their physicians discuss the limitations and potential benefits of screening and the risks of false-positive results and complications from diagnostic procedures. They recommend extending the screening age to 80 years, but do not recommend LDCT screening unless it can be performed in a center with expertise in LDCT evaluation, diagnosis, and treatment. They do not recommend screening asymptomatic patients with chest x rays or sputum **cytology**.

The National Comprehensive Cancer Network (NCCN) guidelines call for screening high-risk people with LDCT or positron-emission tomography/computed tomography (PET/CT), with results determining when the next screening should be performed. In contrast to the ACS and others, the NCCN includes the following risk factors, in addition to tobacco **smoking**:

- exposure to radon, asbestos, or other cancer-causing substances
- other lung diseases
- certain other cancers
- family history of lung cancer
- exposure to secondhand smoke

Breast cancer

There is accumulating evidence that the benefits of regular breast-cancer screening may be negligible. This has resulted in some contentious disagreements. According to the ACS:

- All women should practice "breast self-awareness"—familiarity with the appearance and feel of their breasts, so a physician can be consulted immediately upon noticing any changes.
- Breast self-examination (BSE) is an option for women beginning in their 20s.
- All women aged 20–39 should have a clinical breast exam (CBE) performed by a healthcare provider about every three years.
- Women aged 40 and older should have annual mammography and CBE, preferably at the same time, continuing for as long as they are healthy enough to be candidates for breast-cancer treatment.
- Women at moderately increased lifetime risk (15–29%) should consult their physicians about adding magnetic resonance imaging (MRI) to their annual mammography.
- Women diagnosed with non-invasive breast cancer (lobular carcinoma in situ; LCIS) may be advised to continue annual mammography to monitor the cancer rather than begin active treatment.

The American Congress of Obstetricians and Gynecologists (ACOG), NCI, and the American College of Radiology generally agree with the ACS in recommending annual mammograms for all women beginning at age 40, although ACOG acknowledges that every two years may be more appropriate for some women, based on individual risk and personal values. ACOG recommends breast self-awareness that can include BSE, as well as CBE every one to three years for women aged 20–39 and annually for women 40 and over. ACOG does not recommend MRI for women at average risk. ACOG and Kaiser Permanente Care Management Institute (KPCMI) recommend that women aged 75 and older consult with their physicians about whether to continue screening.

The USPSTF and KPCMI do not recommend routine mammography for women aged 40–49; rather, screening decisions should be made by the patient and her physician based on potential harms, benefits, and the woman's preferences, values, and individual risk. For women aged 50–74 of average risk, the USPSTF recommends mammography once every two years, and KPCMI recommends one- or two-year intervals. The USPSTF recommends against teaching BSE to women. They state that women at increased risk may need to begin mammography screening at an earlier age, have more frequent exams, or have additional screenings such as **ultrasound** or MRI. As of 2014, the ACS and USPSTF were reviewing their breast-cancer screening guidelines, particularly for women aged 40–49.

Women are at increased risk for breast cancer if they have had previous breast cancer, have a family history of breast cancer, or have a known genetic predisposition. Women with a family history of breast cancer may have genetic screening for mutations in the BRAC1 and BRAC2 genes that may increase their risk

WWW.BOOKBAZ.IR

of breast cancer by up to 80%. Breast cancer caused by these mutations tends to occur at an earlier age and in both breasts. Women with these mutations are also at higher risk for **ovarian cancer**. Genetic screening also may identify mutations in other genes associated with breast cancer.

Cervical cancer

ACS and other guidelines are in general agreement:

- Pap tests should begin at age 21, not before, regardless of risk factors, and continue every three years until age 29, with HPV tests only if a Pap test is abnormal.
- Women aged 30–65 should preferably have a Pap test and an HPV test ("co-testing") every five years, but a Pap test alone every three years is acceptable.
- Women over 65 who have had regular normal test results should no longer be tested. Women with a history of serious cervical precancerous conditions should be tested for at least 20 years after diagnosis, regardless of whether they turn 65.
- Women who have had their uterus and cervix removed and have no history of cervical cancer or serious pre-cancer should not be tested.
- Women who have been vaccinated against HPV should continue to follow the above screening recommendations.

Women at higher risk for cervical cancer should be screened more frequently. The ACS guidelines call for annual screenings to continue as long as a woman remains in good health. Women at higher risk include those who:

- have new risk factors
- had abnormal Pap or HPV test results within the past three years
- were exposed to diethylstilbestrol (DES) before birth
- had previous cervical cancer
- are infected with HIV or have a compromised immune system due to chemotherapy, chronic steroid use, or an organ transplant

Ovarian cancer

Women with a hereditary ovarian cancer syndrome or are known to have BRAC1 or BRAC2 gene mutations should have annual or semi-annual pelvic exams, cancer antigen (CA-125) blood tests, and possibly **transvaginal ultrasound**. The USPSTF recommends against screening for ovarian cancer in women without symptoms who are not at high risk.

Endometrial cancer

ACS guidelines emphasize that screening is not necessary for women who have no identified risk factors. Women with or at high risk for HNPCC should have an annual **endometrial biopsy** beginning at age 35. Women with particular medical histories also may need to consider yearly endometrial biopsies. The ACS urges that all menopausal and postmenopausal women be informed about the risks and symptoms of **endometrial cancer** and encouraged to immediately report any unexpected vaginal bleeding or spotting to their doctors.

Prostate cancer

Guidelines agree that the decision to start or continue PSA-based screening should occur only with full understanding of the possible benefits and harms and the patient's preferences and values. Men of African descent or with a father or brother diagnosed with prostate cancer at an early age (before 65) are considered at increased risk. Men with more than one first-degree relative affected at an early age are considered to be at high risk.

- The ACS does not recommend routine screening; rather, men aged 50 and older without symptoms and at least a ten-year life expectancy should make an informed decision in consultation with their doctors. Those at increased risk should talk to their doctors about PSA screening, with or without a DRE, beginning at age 45. Men at high-risk because of multiple family members diagnosed with prostate cancer before age 65 should discuss screening with their doctors beginning at age 40. Screening frequency depends on PSA levels.
- The American Urological Association recommends against screening men under age 40 and does not recommend routine screening for men aged 40–54 of average risk or screening of men over age 70 or with a life expectancy of less than 10–15 years. For men who decide to be screened, routine screening at intervals of two years or more is preferable to annual screening, since this interval appears to preserve the majority of screening benefits while reducing false positives and over-diagnoses.
- The USPSTF recommends against PSA-based screening, since the potential harm associated with the screening as practiced in the United States outweighs the benefits for men without symptoms. Both PSA and DRE screening should be discontinued at age 75 and in men with a chronic medical condition or a life expectancy of less than 10 years.

KEY TERMS

BRCA1 and BRCA2—BReast CAncer susceptibility genes; certain mutations in these genes greatly increase the risk for breast cancer, as well as ovarian cancer.

Breast self-exam; BSE—A five-step monthly procedure for women to detect lumps or other changes in their breasts.

Clinical breast exam; CBE—An examination performed by a healthcare provider to detect lumps or other irregularities in the breasts.

Colonoscopy—An examination of the rectum and colon with a long flexible instrument passed through the anus that can remove polyps and cancerous lesions.

Colorectal cancer; CRC—Cancer of the colon or rectum.

Computed tomographic colonography; CTC—Virtual colonoscopy; visualization of the rectum and colon using a computer to collate multiple x rays into three-dimensional views.

Digital rectal exam; DRE—A physical examination of the rectum and pelvis.

Familial adenomatous polyposis; FAP—An inherited disease characterized by numerous polyps in the colon and rectum that usually become cancerous.

Fecal immunochemical testing; FIT—Antibody testing for blood in a stool sample.

Fecal occult blood testing; FOBT—Laboratory testing for blood in a stool sample.

Guaiac smear testing; gFOBT—Guaiac fecal occult blood testing; a screening test for hidden (occult) blood in the stool.

Hereditary non-polyposis colorectal cancer; HNPCC—Lynch syndrome; inherited colorectal cancer that is not characterized by the development of polyps.

Human papillomavirus; HPV—A large family of viruses, some of which cause cervical and other cancers.

Low-dose computed tomography; LDCT—A lung-cancer screen using multiple low-dose x rays.

Mammography—X-ray screening to detect breast cancer.

Melanoma—A malignant skin tumor that originates in melanocytes (pigmented cells) of normal skin or moles.

Pap test—Pap smear; examination of cervical cells for the early detection of cancer.

Polyp—A projected mass of swollen or tumorous membrane.

Prostate-specific antigen; PSA—An enzyme secreted by prostate cells; PSA levels in the blood are sometimes used to screen for prostate cancer.

Sigmoidoscopy—An examination of the rectum and lower colon with a flexible instrument passed through the anus that can remove polyps.

Stool DNA testing; sDNA—Stool sample testing that detects abnormal DNA from polyps or cancer.

- The NCCN suggests that men who want screening, especially those at increased risk, have a baseline PSA test at age 40 and, if negative, be screened every two years.

Other guidelines

The ACS recommends that people 20 and older who have periodic health exams have a cancer-related checkup that includes health counseling and, depending on age and gender, exams for cancers of the skin, thyroid, oral cavity, lymph nodes, and ovaries or testes. The USPSTF states that there is insufficient evidence to recommend for or against screening for oral or **bladder cancer** in adults without symptoms. It recommends against screening for **testicular cancer**.

Risks

There is increasing recognition of the potential risks of cancer screenings.

- CRC stool tests, Pap tests, and PSA can yield false-positive and false-negative results.
- Invasive procedures, such as sigmoidoscopy and colonoscopy, carry a small risk of tissue damage or infection and a very small risk of significant bleeding or puncture of the colon or rectum that, rarely, may require surgical repair. Colonoscopy carries more risk of complications than sigmoidoscopy because it examines the entire large intestine.
- Mammography sometimes fails to detect cancerous tissue or detects lumps that are normal breast tissue or would never cause problems but can result in over-treatment.
- Some prostate cancers may never cause symptoms or become life-threatening, yet treatment can result in harmful side effects.
- Detection of prostate cancer may not improve health or life expectancy if the cancer has spread to other parts of the body.

Cancer staging

Definition

Cancer staging is a process used by doctors to determine the location of cancer in a patient's body and how severe the cancer might be. The staging information helps doctors plan how to treat the cancer and to predict a patient's prognosis, or outlook.

Description

Staging cancer helps to define a person's cancer. Cancer is the uncontrolled growth and division of cells in the body. When the cells grow out of control, they may form a mass, or tumor. Tumors that become too large begin to invade healthy tissues and organs nearby and cause symptoms, pain, or health problems. When a tumor grows in place, it is local. If it spreads into nearby tissues, doctors may call it regional spread or local-regional spread.

Uncontrolled cell growth also can affect the balance of cancer cells to healthy cells in the body, such as in blood cancers. As cancer cells multiply, some can break off from a tumor and enter a person's blood or lymphatic system. If this happens, the cancer spreads from its primary site (where the original tumor formed) to a distant site. This type of spread is called mestastasis.

The size of a tumor and where its cancer cells spread can indicate its stage and how it should be treated. This is important information used in many cancer staging systems, including the American Joint Committee on Cancer (AJCC) staging system, which is used to stage many cancers in the United States.

American Joint Committee on Cancer Staging System

The AJCC staging system, also called the TNM system, is one of the most common systems in use. It relies on laboratory testing, diagnostic imaging, and biopsy information to examine three main factors about cancers. T stands for tumor; N stands for lymph node; and M stands for mestastasis. The staging system assigns a number to each grouping that may indicate a finding such as the size of a tumor, then a number to the final stage, which is determined by combining specific information from the T, N, and M groupings.

TUMOR. The tumor (T) category measures the size and behavior of the primary tumor, or original site of the cancer, according to:

- TX, which means the tumor could not be assessed
- T0, which means doctors found no evidence of a tumor
- Tis, cancer cells located only in the original tissue
- T1-T4, which is based on the size of the tumor and how much it has invaded nearby tissues

LYMPH NODES. The lymph node (N) category assesses whether cancer cells have spread into lymph nodes near the primary tumor, according to:

- NX, which means the lymph nodes cannot be assessed
- N0, which means doctors found no evidence of cancer in nearby lymph nodes
- N1-N3, which is based on where lymph nodes have cancer cells, how large they are, or how many nodes are involved

METASTASIS. The metastasis (M) category measures the spread of the original cancer to distant tissues or organs, according to:

- MX, which means metastases cannot be assessed
- M0, which means doctors found no evidence of metastasis
- M1, which means there is evidence of distant metastasis

WWW.BOOKBAZ.IR

Staging specific cancers

The AJCC system uses specific information from the TNM findings to help define cancer stage for major cancers. Stages range from 0 to IV, using Roman numerals. Stage 0 is the earliest stage, and stage IV is the most advanced stage. Once a patient's cancer stage is determined, it does not changed, even though the patient's condition improves with treatment or a tumor shrinks or goes away. The term restaging is used, however, to refer to describing cancer after treatment or cancer that returns, or recurs.

As researchers and doctors learn more about cancer cells and genetics, other information is used in cancer staging as well. Some cancers involve different types of cells that affect treatment and outcome for patients. And tumor markers, or indicators of cancer, can affect how the disease is staged. An example is the prostate specific antigen (PSA), which is used in diagnosing and staging prostate cancer in men.

Staging example

An example from breast cancer demonstrates how TNM cancer staging works. A patient is told she has stage IIIC cancer. Doctors arrived at the stage by determining that the patient had any T, combined with N3 and M0. This means that the patient had a breast tumor of any size, cancer cells that had spread to particular lymph nodes around the collarbone or underarm area that are not the closest lymph nodes to the tumor, and possible in some lymph nodes inside breast tissue. In addition, the patient has no spread of the cancer to distant organs. Based on the staging, the patient would receive a combination of breast-conserving surgery, lymph node removal, radiation therapy, chemotherapy, hormone therapy, and targeted therapy. Specific treatment would depend on whether the tumor can be removed surgically.

Origins

In the 1760s, a Scottish surgeon named John Hunter had described "movable tumors" and compared them to those that were immovable, or more advanced. He advised that doctors only remove movable tumors because immovable ones were beyond treatment. In essence this was the first crude form of cancer staging. A German researcher named Theodor Schwann first recognized the role of multiplying cells in cancer, and put a description to metastasis in the mid-nineteenth century.

By the early 1960s, a doctor at Stanford Hospital in California named Henry Kaplan began to precisely match early, local forms of Hodgkin's disease to treatment. Now called Hodgkin's lymphoma, the cancer of the immune system begins in the lymph vessels or organs. Kaplan realized that early forms of Hodgkin's were very different from those diagnosed at later stages, after the disease had spread throughout a patient's body. He also recognized that the early and widespread forms of the disease should be treated differently. The AJCC has helped lead cancer staging in the United States since publishing its first manual of staging systems in the late 1970s.

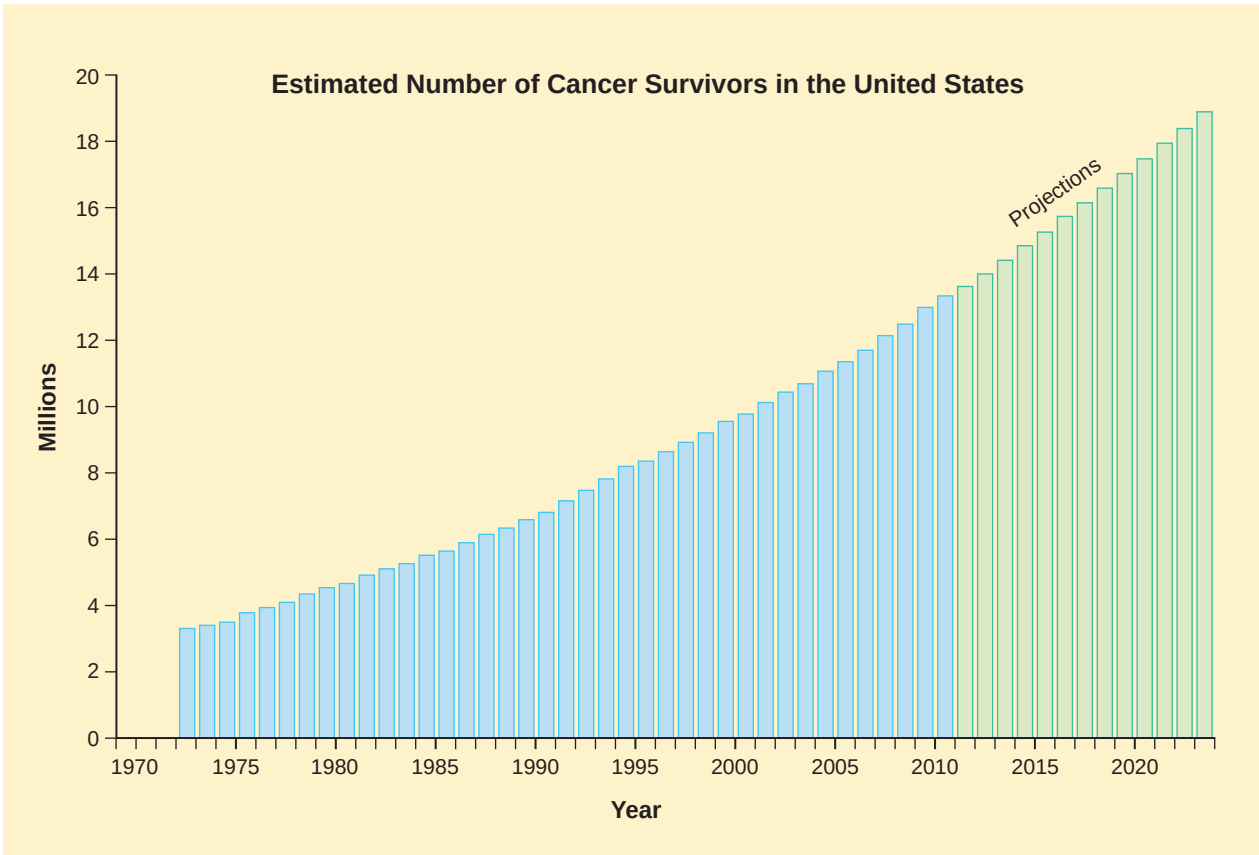
Cancer survivorship issues

Definition

Cancer survivorship issues refers to a range of physical, emotional, financial, interpersonal, and spiritual/religious concerns related to being diagnosed with and treated for cancer. "Cancer survivorship" itself does not have a universally accepted definition. In the United Kingdom, a cancer survivor is most



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

often defined as "someone who is living with or beyond cancer." In the United States, both the National Coalition for Cancer Survivorship (NCCS) and the National Cancer Institute (NCI) have a very broad definition of cancer survivorship that includes friends and family members: "An individual is considered a cancer survivor from the time of diagnosis through the balance of his or her life. Family members, friends, and caregivers are also impacted by the survivorship experience and are therefore included in this definition." The M.D. Anderson Cancer Center defines a survivor more simply as "anyone who's been diagnosed with cancer. Survivorship starts at the time of disease diagnosis and continues throughout the rest of the patient's life."

It is important to note, however, that some people who have had cancer dislike the term "survivor" because it suggests that they are passive victims; they prefer terms like "aliver" or "thriver." Others feel that "survivor" minimizes or devalues those who are dying of incurable cancer; in short, that it glosses over the range and variety of human experiences that involve cancer diagnosis or treatment.

Demographics

Cancer survivorship has become a subject of concern in part because of the sheer number of people who are alive 5 years or more after having been diagnosed with cancer. The NCI stated that as of January 2014, there were 14.5 million cancer survivors in the United States—about 4% of the population. Sixty percent of these people were 65 years old or older. Sixty-four percent survived five years or more after diagnosis, with 41% living 10 years or longer and 15% living 20 years or more. Within the next decade, the number of cancer survivors is expected to increase by 37%, to 11.9 million.

The most common types of cancer represented among cancer survivors in the United States are cancers of the female breast (22%); the prostate (21%); colorectal cancer (9%); and gynecologic cancers (7%).

Historical background

Cancer survivorship is a relatively recent issue because survival rates were quite low until the 1980s. As recently as 1960, only 25% of cancer patients lived

WWW.BOOKBAZ.IR

five years or longer post diagnosis; in the 1980s the figure approached 50% and was close to 65% as of 2014. When survival rates were low, however, little attention was paid to the minority of patients who did survive.

Fitzhugh Mullin, a physician, wrote the article that is often credited with starting the survivorship movement. Mullan was then in his mid-30s, and the article was published in the *New England Journal of Medicine* in July 1985. Mullan described his experience with thoracic cancer as falling into three "seasons of survival," which he termed acute, extended, and permanent survival. He closed by stating that the United States needed "a strategy for survivorship," a national effort to "investigate and address the problems of survivors." Within a year, the NCCS was founded, and the NCI opened its Office of Cancer Survivorship (OCS) ten years later, in 1996. The OCS continues to conduct research into issues of cancer survivorship.

Description

The issues facing cancer survivors are complex and wide-ranging. On the one hand, the experience of survivorship is highly individual; no two cancer survivors will have identical experiences with diagnosis and treatment because of differences in age, sex, cancer type, occupation, geographic location, financial circumstances, spiritual or religious beliefs, and family or friendship networks at the time of diagnosis. However, the issues that confront survivors can be grouped together under general terms.

Stages of survivorship

Some health care professionals still find it helpful to describe survivorship as occurring in three phases or stages, similar to Mullan's "seasons of survival," on the grounds that a person's concerns change over the course of treatment. The M.D. Anderson Cancer Center distinguishes these phases as follows:

- Living with cancer: this phase includes the diagnosis and the treatments that follow. This is the phase in which patients generally have the most intensive contact with their treatment team, which typically includes physical therapists, pharmacists, social workers, and dietitians as well as surgeons, oncologists, nurse practitioners, and psychotherapists. Most survivors prefer to set up an individualized survivorship care plan (SCP) during this phase. SCPs were first discussed and recommended during an Institute of Medicine (IOM) workshop in the fall of 2006; sample SCPs were included in the IOM's follow-up report published in 2007.
- Living through cancer: this phase is the period following treatment when the risk of cancer recurrence is still relatively high. Survivors in this phase typically see their oncologist 2–4 times a year but may feel anxious about the infrequent contact.
- Living beyond cancer: this phase refers to post-treatment and long-term survivorship. Most survivors return to the care of their primary physician. About two-thirds of survivors in this phase state that their lives have returned to normal, but the remaining third struggle with ongoing physical, financial, or interpersonal problems.

Physical issues

Physical issues are usually the first and often the most distressing issues confronting cancer survivors. They may be caused by the cancer itself, by the

KEY TERMS

Body image—A person's sense of his or her physical appearance, often shaped by social standards of attractiveness as well personal experiences.

Chemo brain—A term used to describe problems with memory, concentration, or thinking clearly following chemotherapy.

Lymphedema—A condition that occurs when lymph nodes under the arm are removed by surgery or damaged by radiation therapy as part of breast cancer treatment. Fluid build-up in the affected area results in pain and sometimes partial loss of arm function.

Peripheral neuropathy—Spontaneous tingling or burning sensations in the extremities, or muscle twitching or muscle weakness due to nerve damage resulting from cancer therapy.

Survival guilt—A feeling of guilt about having done something wrong by surviving some event or experience when others did not. It is also called survivor's guilt or survival syndrome.

Survivorship care plan (SCP)—The record of a patient's cancer history and recommendations for follow-up care. It details the responsibilities of all care providers, whether cancer-related, primary care, or psychosocial. The SCP is intended to improve the survivor's care coordination and avoid duplication of resources.

treatments, or by the side effects of treatments, and they may affect almost any body system. Common physical problems include:

- fatigue (most common physical symptom reported by cancer survivors)
- dental problems and nutritional imbalances, including gum diseases and tooth decay caused by treatments or difficulty swallowing and, as a result, maintaining adequate nutrition
- endocrine disorders caused by steroid medications and hormone therapy used to treat cancers of the reproductive system; may lead to chronic disorders ranging from type 2 diabetes and hypothyroidism to hair loss, depression, impotence, loss of muscle mass, and weight gain
- pain
- premature aging
- loss of fertility and sexual functioning
- lymphedema, a condition in which lymphatic fluid accumulates in the tissues near the arm following treatment for breast surgery
- organ damage caused by chemotherapy drugs
- peripheral neuropathy—a tingling or burning sensations, muscle twitching, or muscle weakness in the extremities—due to nerve damage
- osteoporosis and bone loss from cancers of the bone or treatments for breast and prostate cancer

Emotional issues

Emotional difficulties commonly affect cancer survivors. Depression can result from pain, fatigue, and other physical side effects of cancer therapy; anxiety may be related to fear that the cancer will recur; and mood swings, anger, and a tendency toward isolation also frequently occur. Family members as well as survivors themselves may develop post-traumatic stress disorder (PTSD)—about 10% of cancer survivors meet the criteria for major depressive disorder and another 20% meet the criteria for PTSD. Suicidal thoughts are common among cancer survivors.

Other emotional issues related to cancer survivorship include damage to body image (particularly common following facial disfigurement or the loss of body parts) and survival guilt, which is a sense of guilt or of having done something wrong related to having survived the cancer when others did not.

Financial issues

Financial issues are problematic for almost all cancer survivors due to the high costs of treatment combined with the possible loss of income from taking leave of absence from work. The cost of a year's treatment can easily run between $100,000 and $200,000. In some cases, family members may also have to leave work, at least temporarily, to care for the survivor. Financial worries, in turn, may intensify the survivor's anxiety, depression, or other emotional reactions.

Survivors who do return to work often struggle with questions of what and how much to tell their employers for fear of job loss and health insurance. Others may feel that there is a barrier between them and coworkers who have not undergone a life-changing event such as cancer. Still others worry about fatigue and whether they will be able to perform on the job as well as they did before the diagnosis. A specific concern for some survivors is "chemo brain," a term used to describe memory loss, difficulty concentrating, and a lowered ability to think clearly following chemotherapy.

Family/relationship issues

Many survivors worry about the impact of their cancer on family ties and friendships. Caregivers are at increased risk of stress-related illnesses and may suffer from the same anxiety and depression as the survivor. They may also feel anger and resentment about increased financial and social burdens. Some may also "shut down" emotionally and avoid discussing their feelings or even ordinary household matters with the survivor. Lack of communication can be particularly painful when there are children in the household, who may not understand why there is tension in the family, and the survivor parent may feel guilty about frequent absences during treatment.

One specific area of concern for survivors who are married or in an intimate relationship is sexual intimacy. Survivors may be concerned about fertility and possible childbearing (for young adults); need for genetic counseling, if the cancer is hereditary; and changes in the appearance and functioning of one's body. Chronic pain and fatigue may also affect a couple's intimate relationship.

Spiritual issues

It is not unusual for cancer survivors to find that their experience has sharpened their appreciation of the good things in life and prompted them to take stock of what is centrally important to them. For many people, this renewed focus or sense of purpose takes the form of religious worship within a faith community and/or such spiritual practices as meditation. Such activities as journaling, artistic activities, or

WWW.BOOKBAZ.IR

participation in a musical group also help survivors to reconnect with beauty and creativity.

Special concerns of young survivors

Adolescent and young adult survivors of cancer, sometimes referred to as AYAs, have special concerns about survivorship. They are a relatively new subgroup of cancer survivors, as childhood cancer was almost universally fatal before 1970. By 2000, however, the five-year survival rate for childhood cancer had risen to 80%. As of 2014, there were about 270,000 survivors of childhood cancer in the United States, or about 1 in 640 youths.

Special issues for AYAs include education as well as future employment; unlike adult cancer survivors, AYAs have not completed their educations prior to diagnosis and treatment, and may have concerns about how their medical histories will affect college admissions decisions and future employment prospects. They may struggle with learning difficulties associated with "chemo brain," and may be worried that entire occupations will be closed to them because of their need for long-term follow-up care or the side effects of cancer treatment. They may have the same concerns as adult survivors about intimate relationships and sexual functioning, intensified by the self-consciousness that affects adolescene. About 13% of AYAs report being troubled by suicidal thoughts.

Another major concern for adolescent and young adult survivors is the increased risk of complications related to cancer treatment and the greatly increased risk of devloping a second malignancy during their lifetime. About two-thirds of AYAs will develop at least one serious complication as a result of cancer therapy, and one in three will develop a life-threatening complication. The increased risk of a second cancer in AYAs is thought to result from the heightened intensity of the chemotherapy or radiation therapy compared to the levels given to adults.

End-of-life issues

Some health care professionals believe that people with terminal cancer are overlooked or placed to one side in discussions of survivorship issues. This discomfort with those whose survival is measured in weeks or at most months may be related to the fact that the dying cannot represent the "ideal" cancer survivor. One side effect of the type of survivor story that frequently appears in the mass media has been the emergence of this ideal. The media often publicize survivors who are larger-than-life, super-people who return to work without difficulty; have happy marriages and healthy children; and achieve significant athletic, artistic, or professional success. Survivors who are moving toward the end of life may feel like "failures" when measured against this unrealistic image of survivorship, which may add to their distress. It is important for health professionals, family, and friends to be as supportive of people who are at the end of life as they are of long-term survivors.

Resources

The emergence of the survivorship movement since the mid-1980s has led to the formation of a wide range of organizations, networks, support groups, and clinics to help survivors move ahead with their lives after treatment ends. One of the earliest resources was the NCCS's Cancer Survival Toolbox, first published in 1998. The Toolbox is a series of audio programs intended to help survivors navigate the interpersonal, financial, and other complications that arise during survivorship. A downloadable PDF version of the Toolbox is also available. The American Society of Clinical Oncology (ASCO) has also published a guide for survivors that includes sections for noting important information and making plans for long-term follow-up as well as lists of questions to ask the survivor's doctors.

The M.D. Anderson Cancer Center has survivorship clinics for 11 different types of primary cancers that offer surveillance, early detection of recurrence, management of late effects of cancer, and help with the various psychosocial issues that arise. Other major cancer centers in the United States offer assistance with long-term care plans as well as suggestions for coping with such issues as fear of recurrence. Most cancer centers also provide referrals to social workers or financial planners who can help with money-related concerns.

Survivor support groups and networks include Internet-based chat rooms as well as face-to-face meetings. Many of these are intended for survivors of a particular type of cancer, but others are open to any survivor. The ACS maintains a database of local support groups around the United States as well as links to online support groups and chat rooms under its sponsorship, located online at: http://www.cancer.org/treatment/supportprogramsservices/index.

Cancer therapy, curative intent

Definition

Curative intent cancer therapy is a treatment plan designed to control and potentially cure cancer using one intervention or a combination of interventions, including surgery, radiation, **chemotherapy**, and biological or targeted therapies.

Description

Surgery

Surgical removal of the tumor must be performed with care and accuracy. The surgeon must avoid overmanipulation of the surgical field. Too much movement within the area can cause cancer cell displacement into surrounding tissue. If this occurs and no further treatment is administered, the tumor may grow again. The surgeon also should perform an assessment concerning tissue removal around the cancer site. Tissue around the site may not seem cancerous by visual inspection, but adjacent structures may have cancer cells that can only be detected microscopically. Surrounding tissue removal is usually part of the operative procedure. Pieces of tumor and the surrounding area are analyzed microscopically during the operation for cell type. An adequate resection (removal of tissue) will reveal normal cells in the specimens analyzed from areas bordering the cancerous growth.

Surgery can also help to decrease the tumor bulk (size) and, along with other treatment measures, may provide a cure for certain cancers. Surgery generally works best on slow-growing cancers.

Not only can surgery be curative for some cancers, but it is an essential diagnostic tool. Diagnostic procedures that can be done in the surgical environment include an aspiration biopsy, in which a needle is inserted to extract (aspirate) fluid contained inside a cancerous growth; a needle biopsy in which the surgeon uses a specialized needle to obtain a core tissue specimen; an incision biopsy which removes a section from a large tumor; and an excision biopsy, a procedure which removes the entire tumor. The surgeon also can take samples of neighboring lymph nodes. Cancer in surrounding lymph nodes is an important mechanism for spread of cancer to other areas. If microscopic analysis determines the presence of cancer cells in lymph nodes, the surgeon may decide to perform a more aggressive surgical approach.

Radiation therapy

Similar to surgical intervention, **radiation therapy** is a localized treatment. It involves the administration of ionizing radiation to a solid tumor location. This generates reactive oxygen molecules, causing the destruction of DNA in local cells. There are three commonly used radiation therapy beams: gamma rays from a linear accelerator machine produce a focused beam; orthovoltage rays are of less energy and penetrate less and typically deliver higher doses to superficial tissues (efficient for treating skin cancers); and megavoltage rays are high energy producing beams that can penetrate deeply situated internal organs, while sparing extensive skin damage.

Brachytherapy delivers radiation internally by placing radioactive materials such as radioactive seeds and pellets in close proximity or directly into the cancerous tumor. Teletherapy delivers radiation to a specific area of the body using a machine that delivers a beam of radiation from a source that is external to the body.

Chemotherapy

Chemotherapy drugs work by disrupting cancer cell division, which leads to cell death. Combining several different chemotherapy agents with different mechanisms of action and different toxicity profiles often results in more effective therapy and is known as combination chemotherapy. Chemotherapy is considered a systemic therapy because it is typically administered via the blood and circulates through the entire body. The choice of chemotherapeutic agents depends on the specific type of cancer and the effectiveness of the chosen drug(s) on the specific cancer being treated.

Curative chemotherapy usually requires multiple administrations of the chemotherapy drug over several months. This is referred to as a treatment cycle.

Biologic or targeted therapy

Targeted therapies, as the name implies, are designed to target specific molecular flaws of cancer cells. Some drugs in this classification target specific proteins produced by cancer cells, some target cancer cell communication pathways in an attempt to disrupt the pathways, some work to inhibit new blood vessel growth required to sustain a tumor, and other drugs target the pathways in cancer cells that facilitate the ability of cancer cells to metastasize.

Biologic therapies primarily function to alter the patient's response to cancer. These treatments tend to stimulate specific immune cells or immune chemicals to destroy cancer cells.

Purpose

The primary purpose of curative care is to establish a cure and to destroy and remove all cancer cells from the person diagnosed with cancer.

Surgery

Surgery is a diagnostic tool and is also used for **tumor removal**. The surgeon usually identifies potential candidates for tumor removal, which typically occurs during a surgical procedure. Surgery can be curative for some stomach, genital/urinary, thyroid, breast, skin, and central nervous system cancers. The best chance for a surgical cure is usually with the first operation. It is essential that the cancer surgeon (oncologic surgeon) be experienced in the specific procedure.

Radiation therapy

Radiation therapy is administered to many cancer patients during the course of treatment of cancer. This type of treatment can be used as the sole method of cure for tumors in the mouth and neighboring structures in the oral cavity, vagina, prostate, cervix, esophagus. It is also used in cases of Hodgkin's disease and certain types of cancer in the spinal cord and brain. Research and clinical trials have demonstrated that combination treatment is typically more effective than radiation therapy alone.

Chemotherapy

Chemotherapy is curative treatment strategy for some cancers. It is most effective against **choriocarcinoma**, cancer of the testis, some types of lymphomas, and cancer of skeletal muscles.

Biological and targeted therapies

Biological therapies and targeted therapies offer a newer and promising direction for cancer control and cure. Targeted therapies interfere with the actions of specific molecules involved in the growth and progression of cancerous tumors. One type of targeted therapy is directed toward stopping angiogenesis, which is the development of a blood supply to the tumor. Usually when cancer cells grow, they manage to derive a blood supply that allows passage of nutrients promoting continuation of abnormal cancer growth. Treatment that focuses on destroying these blood vessels is called antiangiogenesis therapy. Cutting off the blood supply has been shown to destroy tumors, since this stops the flow of essential nutrients required for cancer growth.

Other examples of targeted therapies include use of certain growth factors that can stimulate self-destructive pathways in cancer cells (apoptosis) and **gene therapy**, which is directed toward inhibiting specific cellular signals that promote cancer cell multiplication.

Precautions

Surgical resection requires an experienced surgeon and surgical team, preoperative assessment, imaging studies, and delicate operative technique. Care should be taken during the procedure to avoid unnecessary tumor manipulation, which can cause cancer cells to infiltrate adjacent structures. If manipulation is excessive, cells can enter nearby areas for future re-growth. Accurate isolation of the tumor also can help avoid contamination of the surgical area. Early ligation of the blood supply to the tumor is an essential component of a surgical cure.

Radiation therapy requires extensive treatment planning and imaging. Care must be taken to localize the cancer treatment field while attempting to spare normal tissue from the effects of radiation. This requires image monitoring and exact positioning during radiation treatment sessions.

Chemotherapy usually causes destruction of normal cells, and some cancer cells can develop immunity or become refractory to the effects of chemotherapy. These agents must be administered only by experienced clinicians who have been educated specifically in their administration. Side effects and patient tolerance issues typically are anticipated, and dosages may have to be specifically altered.

Biological or targeted therapies may cause severe side effects. The side effect profile of biologic or targeted agents is usually different from the side effect profile of chemotherapy agents. Side effects of biologic or targeted agents are usually specific to the classification of the drug, whereas some drugs have their own unique side effects.

Preparation

For all treatment methods, imaging studies, biopsy, and constant blood analysis are essential before, during, and after treatments. Surgical candidates should undergo extensive preoperative evaluation with imaging studies, blood chemistry analysis, stabilized health status, and readiness of staff for all possible complications and cell biopsy analysis. Patients with other preexisting chronic disease may require intensive postoperative monitoring.

WWW.BOOKBAZ.IR

KEY TERMS

Bone marrow suppression—A decrease in cells responsible for providing immunity, carrying oxygen, and those responsible for normal blood clotting.

DNA—The molecule responsible for cell multiplication.

Titrate—To analyze the best end point (for dose) for a medication.

Prior to radiotherapy, the patient undergoes extensive imaging studies. Additional planning strategies include beam localization to spare normal tissues, calibration of fractionated doses, and specific positioning during treatment sessions.

Patients who receive curative chemotherapy should be informed of possible side effects associated with the drug they are given. Patients should also be informed of temporary lifestyle changes and medications that may offer some symptom relief.

Patients undergoing biologic or targeted therapies should be advised of potential side effects, treatment cycles, and specific tests for monitoring progress.

Aftercare

Patients are typically evaluated by imaging studies, blood analysis, and **physical examination**, and they are observed for response to treatment. These follow-up visits usually occur at specific intervals during the course of treatment. Surgical patients may require closer observation during the initial postoperative period to avoid possible complications. **Reconstructive surgery** can be considered to improve the patient's appearance and restore function. Certain surgical procedures (such as flaps and **microsurgery** of blood vessels) can restore new tissues to a previous surgery site.

Risks

Surgical risks

Surgical therapy can be both disfiguring and disabling. Any surgical procedure contains a risk for complications during and after the procedure. Patients are monitored closely during and after surgery to minimize the risk of complications.

Radiation risks

Many normal tissues can be adversely affected by radiation therapy. Side effects from radiation therapy depend on the area being treated. Common side effects that can occur shortly after a treatment cycle include nausea, **vomiting**, **fatigue**, loss of appetite, and bone marrow suppression (a decrease in the cells that provide defense against infections and those that carry oxygen to cells). Radiation therapy also can cause skin changes in the skin in the treatment field, difficulty swallowing, oral gum disease, and **dry mouth**. Additionally, radiation therapy can cause damage to local structures within the irradiated field.

Chemotherapy risks

Many commonly used chemotherapy agents cause bone marrow suppression as a side effect of treatment. Additionally, cells called platelets—important for normal blood clotting—may be significantly lowered, causing patients to bleed. This may be problematic enough to limit the treatment course. Bone marrow suppression can increase susceptibility to infection. Some chemotherapy agents may also cause **infertility**. Patients commonly have bouts of **nausea and vomiting** shortly after a treatment session. Rapidly multiplying normal cells also are affected such as skin cells (causing blistering and ulceration) and hair cells causing loss of hair, a condition called **alopecia**.

Biologic therapy risks

Biologic therapies can cause patients to develop suppression of cells that help the body fight against infection. As with all other treatment methods for cancer, patients are screened carefully to determine if the benefits of the treatment outweigh its potential risks.

Cancer therapy, palliative

Definition

Palliative cancer therapy is treatment specifically designed to help improve symptoms at the end of life associated with advanced and/or terminal cancer. **Palliative care** has evolved to become an integral component of cancer care and is typically provided by a team of multidisciplinary health care professionals.

Demographics

Currently, it is estimated that approximately 40% of patients diagnosed with cancer—about 550,000 people per year in the United States—will die from their cancer. The end-of-life care of many of these patients will be delivered by professionals skilled in hospice or palliative cancer care.

Description

Palliative care is directed at improving symptoms associated with advanced and incurable cancer. The five major precepts of palliative care, which were delineated as part of the Robert Wood Johnson Foundation-funded Last Acts campaign to improve quality of care at the end of life, include:

- respect for patient wishes and goals related to end-of-life decisions
- provision of comprehensive end-of-life care
- integration of care delivery from a multidisciplinary perspective
- incorporating the caregiver in to the plan of care at the end of life
- developing adequate support systems for the patient, caregiver, and family

Palliative care can include surgery, **radiation therapy**, **chemotherapy**, hormone therapy, and other specialized therapies, as well as treatment of symptoms resulting from cancer, and providing relief from side effects of treatment. The primary objective of palliative care is to improve the quality of the remainder of a patient's life. Treatment usually involves a combination of modalities (multimodality approach) and numerous specialists typically are involved in the treatment planning process. Therapeutic planning usually involves careful coordination with the treatment team. The approach to palliative care also involves easing psychosocial problems and typically incorporates an emphasis on the patient's family.

Causes and symptoms

Some signs of advanced cancer include extreme **fatigue** and weakness that is progressive, unexplained weight loss, **pain**, and **shortness of breath**, especially if the cancer has spread to the lungs.

There is the potential for a wide range of symptoms as the cancer progresses to the advanced or terminal phase. These symptoms include pain, myoclonus, dyspnea, **anxiety**, **delirium**, and noisy breathing or "rattle" among a variety of other symptoms.

Pain is one of the common symptoms associated with cancer. Approximately 75% of terminal cancer patients have pain. Pain is a subjective symptom and thus it cannot be measured using technological approaches. Pain can be assessed using numeric scales (from 1 to 10, 1 is rated as no pain while 10 is severe) or by rating specific facial expressions associated with various levels of pain. The majority of cancer patients experience pain as a result of tumor mass that compresses neighboring nerves, bone, or soft tissues, or from direct nerve injury (neuropathic pain). Pain can occur from affected nerves in the ribs, muscles, and internal structures such as the abdomen (cramping type pain associated with obstruction). Many patients also experience various types of pain as a direct result of follow-up tests, treatments (surgery, radiation, and chemotherapy) and diagnostic procedures (i.e., biopsy).

Diagnosis

Patients typically are informed that their diagnosis is terminal and treatments are directed to improve quality of life and ease suffering at the end of life.

Examination

The physician may perform a **physical examination** to help confirm advanced cancer based on the signs and symptoms the patient is experiencing. Results of

WWW.BOOKBAZ.IR

this physical exam may include evidence of fluid in the lungs or abdominal area. An enlarged liver may be palpated by the physician, or external lumps that are comprised of tumor may be able to be seen and palpated on various areas of the body.

Tests

Blood test results that may confirm advanced cancer include elevated levels of **tumor markers** in the blood, elevated **liver function tests** and liver enzymes, and elevated or decreased white blood cells, red blood cells, and/or platelets, among other findings.

Imaging tests such as x rays and CT, MRI, PET, bone, and **ultrasound** scans may be conducted to determine the location and spread of the cancer.

A comprehensive palliative care assessment should be conducted to evaluate the following:

- benefits and risks associated with continuing treatments and therapies directed at controlling the cancer
- physical symptoms and problems such as pain, anorexia, dyspnea, nausea/vomiting, constipation, fatigue, weakness, alterations with sleep, and delirium, as well as other problems
- psychosocial symptoms and problems including spiritual needs
- the patient's and family's goals and wishes related to end-of-life care
- educational level to determine information needs and requirements
- the impact of cultural beliefs on preferences related to end-of-life care

Treatment

Surgery can be utilized for palliation after careful evaluation and planning. The use of surgery in these cases may reduce the tumor bulk and help improve the quality of life by relieving pain, alleviating obstruction, or controlling bleeding. Radiation therapy for terminal cancer patients can also alleviate pain, bleeding, and obstruction of neighboring areas. A combination of radiation therapy and bisphosphanates offers palliative relief to patients with metastatic bone disease (metastatic disease is cancer that has spread beyond the original site or organ to other areas of the body). Chemotherapy may be helpful to reduce tumor size and provide some reduction to metastatic disease. Long-term chemotherapy patients develop drug resistance, a situation that renders chemotherapeutic treatments ineffective. If this occurs, patients usually are given a second-line medication or, if admission criteria are met, they may participate in an experimental research protocol. Palliative treatments and terminal cancer in combination can cause many symptoms that can become problematic. These symptoms commonly include pain, nausea, **vomiting**, difficulty breathing, **constipation**, **dehydration**, agitation, and delirium. The palliative treatment-planning goal focuses on reducing these symptoms.

Surgery for **tumor removal**, biopsy, or size reduction is associated with postoperative pain and local nerve damage, which may be both severe and difficult to alleviate. Chemotherapy and radiation therapy also can produce nerve damage and severe pain. Additionally, patients with malignant cancer are susceptible to infections such as herpes, **pneumonia**, urinary tract infections, and wound **abscess**, all of which can cause severe pain. Pain associated with cancer and/or treatments can significantly impair the patient's abilities to perform daily tasks and hence impair quality of life. These complications may negatively impact the patient's psychological well-being.

Drugs

Drugs that may be used in palliative care include:

- opioids, benzodiazepines, glycopyrrolate, and scopolamine—used to treat dyspnea in advanced cancer
- appetite stimulants such as megestrol acetate, medroprogesterone acetate, and steroids—used to ameliorate the effects of anorexia/cachexia
- antiemetics such as prochlorperazine, haloperidol, metoclorpramide, 5-HT3 receptor antagonists, and others—used to treat nausea and vomiting
- biscodyl, glycerine suppositories, polyethylene glycol, lactulose, magnesium hydroxide, magnesium cirate, and/or methylnaltrexone—used to treat constipation in advanced cancer
- haloperidol, risperidone, olanzapine, or quetiapine fumarate—used in the treatment of delirium at the end of life

Prognosis

Palliative cancer care is typically offered to patients with six months to one year of life expectancy.

Prevention

Currently, the only way to prevent a cancer from spreading and developing into an advanced or incurable cancer is to detect the cancer prior to metastatic spread and to initiate treatment for the cancer as soon as possible after diagnosis.

Cancer therapy, supportive

Definition

Supportive cancer therapy is the use of medicines to counteract unwanted effects of cancer treatment.

Purpose

Along with their beneficial effects, many cancer treatments produce uncomfortable and sometimes harmful side effects. For example, cancer drugs may cause nausea or **vomiting**. They also may destroy red or white blood cells, resulting in a low blood count. Fortunately, many of these side effects can be relieved with other medicines.

Description

Different kinds of drugs are used for different purposes in supportive cancer therapy. To relieve **nausea and vomiting**, a physician may prescribe dolasetron (Anzemet), granisetron (Kytril), or ondansetron (Zofran). Drugs called colony stimulating factors are used to help the bone marrow make new white blood cells to replace those destroyed by cancer treatment. Examples of colony stimulating factors are filgrastim (Neupogen) and sargramostim (Leukine). Another type of drug, epoetin (Epogen, Procrit), stimulates the bone marrow to make new red blood cells and help patients overcome anemia. It is a synthetically made version of human erythropoietin that is made naturally in the body and has the same effect on bone marrow.

Some physicians who treat cancer recommend that their patients use **marijuana** to relieve nausea and vomiting. This practice is controversial for several reasons. Using marijuana, even for medicinal purposes, is illegal in most states. Also, most of the evidence that marijuana effectively relieves nausea and vomiting comes from reports of people who have used it, not from carefully designed scientific studies called clinical trials. An oral medication that contains one of the active ingredients of marijuana is available with a physician's prescription and sometimes is used to treat nausea and vomiting in patients undergoing cancer treatment. However, the drug, dronabinol (Marinol), takes longer to work than smoked marijuana and may be difficult for patients with nausea and vomiting to swallow and keep down.

In 1997, the National Institutes of Health issued a report calling for more research into medical uses of marijuana. The panel of experts who wrote the report also recommended that researchers investigate other ways of getting the active ingredients of marijuana into the body, such as nasal sprays, skin patches and inhalers. In 2000, the American Cancer Society funded research into a skin patch. A 2003 report said that a University of Kentucky researcher had applied for a patent for the patch which used synthetic cannabinoids.

WWW.BOOKBAZ.IR

Patients who want to use marijuana to relieve side effects of cancer treatment should talk to their physicians and should carefully consider the benefits and risks, both medical and legal.

Recommended dosage

The recommended dosage depends on the type of supportive cancer therapy. The physician who prescribed the drug or the pharmacist who filled the prescription can recommend the correct dosage.

Precautions

Dolasetron, granisetron, and ondansetron

If severe nausea and vomiting occur after taking these medications, patients should check with a physician.

The use of ondansetron after abdominal surgery may cover up symptoms of stomach problems.

People with **liver disease** may be more likely to have side effects from ondansetron.

Colony stimulating factors

Certain cancer drugs reduce the body's ability to fight infections. Although colony stimulating factors help restore the body's natural defenses, the process takes time. Getting prompt treatment for infections is important, even while taking this medicine. A patient should call the physician at the first sign of illness or infection, such as a **sore throat**, **fever**, or chills.

Seeing a physician regularly while taking this medicine is important. This will give the physician a chance to make sure the medicine is working and to check for unwanted side effects.

People with certain medical conditions may have problems if they take colony stimulating factors. In people who have **kidney disease**, liver disease, or conditions caused by inflammation or immune system problems, colony stimulating factors may make these problems worse. People with **heart disease** may be more likely to have side effects such as water retention and heart rhythm problems when they take these drugs. And people with lung disease may be more likely to have **shortness of breath**. Anyone who has any of these medical conditions should check with his or her physician before using colony stimulating factors.

Epoetin

This medicine may cause seizures (convulsions), especially in people with a history of seizures. Anyone who takes these drugs should not drive, use machines or do anything else that might be dangerous if they have had a seizure.

Epoetin helps the body make new red blood cells, but it cannot do its job unless there is plenty of iron in the body. The physician may recommend taking iron supplements or certain **vitamins** that help get iron into the body. Following the physician's orders to make sure the body has enough iron for this medicine makes it work. Iron supplements should not be taken unless they are prescribed by a physician.

In studies of laboratory animals, epoetin taken during **pregnancy** caused **birth defects**, including damage to the bones and spine. However, the drug has not been reported to cause problems in human babies whose mothers take it. Women who are pregnant or who may become pregnant should check with their physicians for the most up-to-date information on the safety of taking this medicine during pregnancy.

People with certain medical conditions may have problems if they take this medicine. For example, the chance of side effects may be greater in people with high blood pressure, heart or blood vessel disease, or a history of **blood clots**. Epoetin may not work properly in people who have bone problems or sickle cell anemia.

Research continues on the benefits of epoetin as a supportive cancer therapy. One 2003 report said new research showed doubt as to its effectiveness in treating anemia, while other reports confirmed it worked well. In mid-2003, a large clinical trial (CREATE) was beginning in England to help determine epoetin's effectiveness.

Dronabinol

This medicine contains sesame oil and one of the active ingredients of marijuana. Anyone who has had allergic or unusual reactions to sesame oil or marijuana products should let his or her physician know before taking dronabinol.

Because dronabinol works on the central nervous system, it may add to the effects of alcohol and other drugs that slow down the central nervous system. Examples of these drugs are **antihistamines**, cold medicine, allergy medicine, sleep aids, medicine for seizures, tranquilizers, some **pain** relievers, and **muscle relaxants**. Dronabinol also may add to the effects of anesthetics, including those used for dental procedures. Anyone taking dronabinol should not drink alcohol and should check with his or her physician before taking any of the drugs listed previously.

This drug makes some people feel drowsy, dizzy, lightheaded or "high," with a sense of well-being. Because of these possible reactions, anyone who takes dronabinol should not drive, use machines or do anything else that might be dangerous until they have found out how the drug affects them. The **dizziness**

and lightheadedness are especially likely when getting up after sitting or lying down. Getting up gradually and holding onto something for support should lessen the problem.

In laboratory studies, giving high doses of dronabinol to pregnant animals increased the risk of the unborn baby's death. The medicine's effects on pregnant women have not been studied. Women who are pregnant or who may become pregnant should check with their physicians before taking this medicine.

Dronabinol passes into breast milk and may affect nursing babies whose mothers take the medicine. Women who are **breastfeeding** their babies should check with their physicians before using dronabinol.

Because of its possible mind-altering effects, dronabinol should be used with care in children and older people. Both children and older people should be watched carefully when they are taking this medicine.

Using dronabinol may worsen some medical conditions, including high blood pressure, heart disease, **bipolar disorder**, and **schizophrenia**.

General precautions for all types of supportive cancer therapy

Anyone who previously has had unusual reactions to drugs used in supportive cancer therapy should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

Side effects

Dolasetron, granisetron, and ondansetron

The most common minor side effects are **headache**, dizziness or lightheadedness, drowsiness, **dry mouth**, **diarrhea**, **constipation**, abdominal pain or stomach cramps, and unusual tiredness or weakness. These problems usually do not require medical treatment.

A physician should be notified as soon as possible if fever occurs after taking granisetron.

If any of these symptoms occur after taking ondansetron, the patient should check with a physician immediately:

- breathing problems or wheezing
- chest pain or tightness in chest
- skin rash, hives or itching

Colony stimulating factors

As this medicine starts to work, it may cause mild pain in the lower back or hips. This is nothing to worry about, and it will usually go away within a few days. If the pain is too uncomfortable, the physician may prescribe a painkiller. A physician needs to know if the painkiller does not help.

Other possible side effects include headache, joint or muscle pain, and skin rash or **itching**. These side effects usually go away as the body adjusts to the medicine and do not need medical treatment. If they continue or interfere with normal activities, a physician should be notified.

Epoetin

This medicine may cause flu-like symptoms, such as muscle aches, bone pain, fever, chills, shivering, and sweating, within a few hours after it is taken. These symptoms usually go away within 12 hours. If they do not, or if they are troubling, a physician should be told. Other possible side effects that do not need medical attention are diarrhea, nausea or vomiting, and tiredness or weakness.

Certain side effects should be brought to a physician's attention as soon as possible. These include headache, vision problems, increased blood pressure, fast heartbeat, weight gain, and swelling of the face, fingers, lower legs, ankles, or feet.

Anyone who has chest pain or seizures after taking epoetin should check with a physician immediately.

Dronabinol

Side effects such as dizziness, drowsiness, confusion and clumsiness or unsteadiness usually do not need medical attention unless they are long-lasting or they interfere with normal activities.

Other side effects or signs of overdose should have immediate medical attention. These include:

- fast or pounding heartbeat
- constipation
- trouble urinating
- red eyes
- slurred speech
- mood changes, including depression, nervousness, or anxiety
- confusion
- forgetfulness
- changes in sight, smell, taste, touch, or hearing
- a sense that time is speeding up or slowing down
- hallucinations

KEY TERMS

Bipolar disorder—A severe mental illness in which a person has extreme mood swings, ranging from a highly excited state—sometimes with a false sense of well-being—to depression

Bone marrow—Soft tissue that fills the hollow centers of bones. Blood cells and platelets (disk-shaped bodies in the blood that are important in clotting) are produced in the bone marrow.

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

Immune system—The body's natural defenses against disease and infection.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Schizophrenia—A severe mental disorder in which people lose touch with reality and may have illogical thoughts, delusions, hallucinations, behavioral problems, and other disturbances.

Sickle cell anemia—An inherited disorder in which red blood cells contain an abnormal form of hemoglobin, a protein that carries oxygen. The abnormal form of hemoglobin causes the red cells to become sickle- or crescent-shaped. The misshapen cells may clog blood vessels, preventing oxygen from reaching tissues and leading to pain, blood clots and other problems. Sickle cell anemia is most common in people of African descent and in people from Italy, Greece, India, and the Middle East.

General advice on side effects for all types of supportive cancer therapy

Other side effects are possible with any type of supportive cancer therapy. Anyone who has unusual symptoms during or after treatment with these drugs should get in touch with his or her physician.

Interactions

Anyone who has supportive cancer therapy should let the physician know all other medicines he or she is taking. Some combinations of drugs may interact, which may increase or decrease the effects of one or both drugs or may increase the risk of side effects. Patients should ask their physician if the possible interactions can interfere with drug therapy or cause harmful effects.

Cancer vaccines

Definition

Cancer vaccines are biological response modifiers that stimulate the immune system. Cancer preventative vaccines are substances that prevent healthy people from developing cancer by targeting infectious organisms that contribute to cancer development. They work in the same way as traditional vaccines (e.g., **mumps**, **measles**, **rubella**, **polio**). Cancer treatment vaccines are a method of treating cancer involving administration of one or more substances characteristic of the cancer, called antigens, often in combination with factors that boost immune function. This induces the patient's immune system to attack and eliminate the cancerous cells.

Purpose

In 2006, the U.S. Food and Drug Administration (FDA) approved the cancer preventative vaccine, Gardasil, that protects against certain human papilloma viruses associated with the development of **cervical cancer**. A second preventative cancer vaccine called Cervarix, which also protects against certain human papilloma viruses, was approved by the FDA in 2009. The only other cancer preventative vaccine approved in the United States is the **hepatitis B** vaccine (HBV or HepB). It is an injection that protects individuals from contracting hepatitis B, a serious disease that contributes to the development of **liver cancer**.

Cancer treatment vaccines are in clinical trials in the United States, but as of 2014, none have been approved by the FDA. Most cancer vaccines are a method of treating cancer that has already occurred and are given to patients already diagnosed with cancer. As a cancer treatment method, the ultimate goal of most cancer vaccines is the elimination of tumor or cancerous cells from the body. Other cancer vaccines are given after the use of more traditional treatments, such as **chemotherapy**, radiation, or surgery, with the aim of suppressing the recurrence of the cancer.

Description

There are four general types of cancer vaccines, those that use whole tumor cells, those that use only one substance derived from the tumors, those using more than one substance derived from tumors, and those that administer primed cells from the patient's immune system.

Whole cell vaccines

Whole cell vaccines are autologous when they contain only inactivated tumor cells from the patient's own tumors. The cells have been isolated from the tumor and made to grow in the laboratory, a process known as creating a cell line. Allogeneic whole cell vaccines are made from inactivated tumor cells isolated from one or more other people. The main advantage to autologous vaccines is the direct relation between the vaccine and the tumor target. However, because of the screening of self antigens away from a body's own immune system, immune response to tumor antigens in autologous whole cells vaccines can be low.

Allogeneic vaccines avoid some of the problems of autologous vaccines. First, cell lines do not have to be created for each patient, a labor-intensive process that can have highly variable results. Second, the same vaccine can be given to all patients, making the response to the vaccine more predictable. Third, using a pool of tumor cells can increase the possibility of having the full repertoire of the tumor antigens in the vaccine. This helps to overcome the ability of tumor cells to escape notice by the immune system. Finally, by using well-characterized cell lines, it is much easier for the researcher to add genetic modifications that increase the immune system's response to the cells.

Isolated antigen vaccines

There are many kinds of vaccines that deliver only a portion of the tumor cell that will elicit an immune response, called an antigen. Some antigens are unique to a cancer type, some are unique to an individual tumor, while a very few are found in more than one cancer type. For example, vaccines against telomerase and human chorionic gonadotripin (hCG), two proteins produced by many cancers, have been developed, raising hopes for the development of a universal cancer vaccine.

The most common kind of antigen used in cancer vaccines is a protein or a part of a protein. The protein can actually be isolated from the tumor cells, or more commonly, produced in large quantity using genetic engineering techniques. When a part of a protein is used, experimental efforts generally preceded the vaccine production to determine what parts of the protein most often are the target of immune responses. Parts of proteins that elicit immune responses are called epitopes.

Antigens do not necessarily have to be proteins. Immune responses are also mounted against the carbohydrate (sugar) molecules present on the surface of the proteins. Tumor proteins can have unusual carbohydrate structures that set them apart from cells of normal tissue. Carbohydrates are also found in abundant numbers on the surface of the tumor cells. Accordingly, researchers have developed cancer vaccines that combine the tumor-characteristic carbohydrates anchored on protein bases. These vaccines are being tested for their ability to reduce the recurrence of **prostate cancer**.

Vaccines can also contain the naked genetic material encoding the protein (either deoxyribose nucleic acid, DNA, or ribose nucleic acid, RNA). After the genetic material gains entry to the cell, the cellular machinery uses it to produce the antigen and an immune response is mounted against it. Animal studies have found that these types of vaccines are very dependent on the particular antigen and the mode of administration of the vaccine. A unique method of delivery used with DNA or RNA vaccines is the coating of tiny gold beads with the genetic material and shooting the beads into the skin.

Genetically engineered viruses can also be used to bring the DNA or RNA into the cell. When used in this way the viruses are called viral vectors. One example of a viral vector being used as a cancer vaccine is based on the adenovirus. When viruses are used as vectors they have been altered to no longer cause disease, but they do retain the ability to infect human cells. Instead of making new viruses, the infected cells make the desired antigen, and the body responds against it. Viral vectors can also carry the genetic instructions for factors, called cytokines, which boost

WWW.BOOKBAZ.IR

the immune system's response to the antigen. This process of using a virus that no longer causes a disease but promotes the creation of antigens is used to develop vaccines to prevent cancer from developing. As of 2014, there are two types of preventative vaccines for cancer; hepatitis B virus for the prevention of liver cancer and **human papillomavirus** vaccines, which reduces one of the main causes of cervical cancer.

Antigen-presenting cell (APC) vaccines

Vaccines can also be made that contain cells from the patient's own immune system called antigen-presenting cells (APCs). These cells play a central role in the development of an immune response against a particular antigen. Specifically, APCs ingest the antigen and present them to the T cells, a type of immune cells responsible for targeting and killing cells seen as foreign to the body. If T cells are exposed to the antigen by an APC, as opposed to seeing the antigen on the cell itself, they are more strongly activated. That is, more T cells that specifically attack that antigen are produced and the immune response against the foreign cell is stronger.

Dendritic cells are a type of APC that is most effective in activating T cells. For this reason, they are often the kind of cells used in APC vaccines. Unfortunately, the number of dendritic cells circulating in the blood at any one time is relatively low. New techniques have been developed that allow that small number of dendritic cells to be isolated and then stimulated outside the body to result in a usable number. During stimulation, the dendritic cells are exposed to the tumor antigen, a process known as priming. When injected into the body, the dendritic cells are primed to recruit large numbers of T cells specific against the tumor antigen.

Cytokines and adjuvants

Since tumor cells are able to escape detection by the immune system, an important component of many cancer vaccines is the addition of biological factors or chemical adjuvants to help boost immune response. One type of adjuvant is a cytokine, a factor normally produced by cells of the immune system to help recruit cells to the site of the foreign cells or help T cells function. Examples of cytokines used in vaccines are granulocyte/macrophage colony stimulating factor (GM-CSF, or sargramostim), the interleukins (especially IL-2), the interferons (INFs), and **tumor necrosis factor** alpha (TNF-α).

Adjuvants are chemical additions to vaccines that help boost the response to the contained cells or antigens. Adjuvants are derived from a variety of sources and can be isolated from animals, plants, or are synthetic chemical compounds. Several adjuvants in use with cancer vaccines are keyhole lympocianin (KLH, derived from shell-dwelling sea animals), incomplete Freud's adjuvant (IFA, mineral oil and an emulsifying agent), and QS-21 (a chemical derived from the soapbark tree).

Administration

The particular administration method and schedule varies for each clinical trial. Administration methods include intradural (injection within the skin), subcutaneous (injection below the skin), injection into the lymph nodes, or intravenous (injection into the veins). Typically, vaccines are administered as a series of several doses (initial challenge and boosters). Many clinical trials utilize various administration methods and timing strategies in order to determine the best means of inducing an anti-tumor immune response. Preventative vaccines are usually given in a series of three injections.

Risks

The greatest risk with cancer vaccines is that there will be no immune response and the treatment will be ineffective. Serious adverse reactions to the antigens, such as the attack of healthy cells, are theoretically possible, but these fears have not materialized. Other than some mild adverse reactions, such as **fever** and redness of the skin at the injection site, vaccine treatment appears relatively low-risk in the traditional sense.

Precautions

No vaccine has yet been approved by the FDA for the treatment of cancer. Accordingly, vaccines are not standard treatments and other more traditional treatments should be investigated first. Vaccines are available only through participation in clinical trials. Each trial has its own criteria that limits who can participate. Many cancers have a current trial for one or more types of vaccines.

Most vaccine trials test the response of the disease with and without the vaccine or the effect of substances added to the vaccine, called adjuvants. Such trials usually only accept patients who have already tried the standard treatment methods. Others test a standard treatment method with and without the addition of the vaccine. A very few compare the standard treatment to the vaccine.

KEY TERMS

Adjuvant—A substance added to a vaccine to increase the immune system's response to the vaccine contents.

Allogeneic—A type of vaccine made up of tumor cells derived from persons other than the patient.

Antigen—A substance characteristic of a tumor that evokes an immune response.

Antigen presenting cell—A cell of the immune system that ingests antigens and exposes them to cells of the immune system in a way that activates the cells to seek out and destroy any other cells displaying that antigen.

Autologous—A type of vaccine made up of tumor cells from the patient's own tumor.

Cytokine—A substance made by cells of the immune system that increases the response to a foreign substance.

Dendritic cell—A special type of antigen-presenting cell that is effective in stimulating T cells.

Epitope—A portion of a protein or other molecule that is the specific target of an immune response.
